with an antenna tuner. The antenna tuner gave me a much broader
bandwidth as far as SWR is concerned without having to retune.

On the other hand, you are not operating mobile. I don't know how
this compares. I know when I did it, it gave me a very weak, but
readable signal. I had a ground rod in the ground below my window. I
connected the shield side of my coax to the ground stake and the
center to one end of a long spool of wire. I stretched the wire out
about 1/4 wave on the ground and checked the SWR. It was flat on the
frequency I wanted (I got lucky) so I checked into the then GA SSB Net
on 3975. I was weak, but readable and could pass my traffic.

If you can make loading coils, make a couple with large diameters.
The larger the better. Center load each element and make them so you
can tap to the coil. This will work better than the ham stick. You
may find that tapping at two different points works better for you so
you have a bit of an offset in the electrical lengths of the antennas
on either side of the coax. This is because the impedance of a
shortened dipole antenna is lower than 50 ohms. The offset finds a
better match.

Hope this helps.

The advantage of the tuner with a "fan" or "parallel wire" dipole is that if you put it at the feedpoint, the incredibly tedious pruning process is eliminated. You just have to get a couple wires "about right", and the tuner does the rest (who cares if the resonance is at 13.5 MHz.. that's not a huge change). And, in the "thrown on the roof" sort of scenario, as the roof grunge and moisture changes or the trees grow up or get leaves on them, changing the native Z of the antenna, the tuner automatically compensates.

It's a coax feedline, so it's easy to route. The matching is at the antenna, so the loss in the feedline is less of an issue.

In this sort of thing it *is* useful to have some way to see if the antenna has fallen apart or shorted out or is covered with wet leaves. The tuner will happily tune almost anything, but you have no real way to know if it's actually radiating. I've used a couple techniques.. a monitor receiver with a whip antenna is one; looking at NCDXF beacons or WWV is another.

Cecil,

I have completely stayed away from any comments in this thread, but one thing has caught my attention. You repeatedly refer to the "wave reflection model" almost as if it was the equivalent of the Grand Unified Theory.

I did a little bit of the cheap modern day replacement for research by Googling "wave reflection model". Some 455 references came back. Of course many of those references are irrelevant to the topic at hand, but of the ones that seemed to be related to transmission lines and/or RF, it appears that all of the references come back to you.

I tried adding Ramo, Whinnery, Johnson, Chipman, Slater, Hecht, and Walter Maxwell to the search (one at a time) and came up with no hits, other than your references.

Perhaps your specific interpretation of the writings of the masters to form your "wave reflection model" is part of the source of the disagreement.

Do you have a concise reference to exactly what you mean by "wave reflection model"?

There is no need to explain reflection, interference, conservation of energy, or any other standard wave phenomenon. I am merely seeking the definition of "wave reflection model" or a lead to any other reference that uses that terminology.

The wave reflection model is, of course, the body of
mathematics encompassing the reflection mechanics for
EM waves. Everywhere except on r.r.a.a, it is a subset
of the distributed network model.

But ham radio and the Navy have proved him wrong with the T2FD
testing !
Computor programs designed around Maxwell's laws also prove him wrong.
I suggest you study the under pinnings, if any, by Terman of that
particular point
and then share the "proof" with all of us. Again, you have two vectors
for the
electric and magnetic field at right angles to each other. Using your
own brain
please tell as where the curl vector MUST be to prove your case.
Ofcourse you can
read a lot of books and select a diagram of the vectors involved that
solidifies your position
but I don't think you will find one anywhere. Your HIT and MYTH
aproaches just doesn't work out.

This still makes no sense. You have not described what you are
"compensating" for, and differential amplifiers amplify without
distinction to "in-phase" or "out-of-phase." If it did, you are not
using the right topology because you are using operational amplifier
terminology - the circuit is not an operational amplifier, even by
discrete components.

Nice close-up. Choking of some of the lines seems OK, but not the
coax. So, now where is the schematic of the biasing for these
varicaps? If those two clear insulation lines are going to the loop,
it is going to be hard to apply DC to a dead short - or does that
black shroud cover more than the varicaps?

Thanks for everybody for good comments,
They are quite in balance with the information I have red from net.

The antenna which I am planning is for portable use and should be
easy to erect and transport.

Your remarks led me to some comments:

- Yes the efficiency on 80m may be too low, because of small size.
- Adding center extenders could help but then 75m hamsticks are out of 80m
band
- By using 40m hamsticks and maybe center loading coil and extenders tuning
to 80m possible?
- Then also operating on 40m without extenders OK
- 80 operation only needed for domestic qsos, no DX
- On 30m and 20m hamstick dipole would work OK

Any comments on these?

Cecil, he is not interested in finding the new,
he is more comfortable of staying with the old
people of his era. He doesn,t need proof and
doesn.t know how to handle it. Terman is the one thing left in life
he has, maybe we should leave him alone for eventual sainthood
ceremonies for Terman when they get to the milky way.
If he is looking for the Proof at the present time then we may
never hear from him again. No one has come to his aid with
a computor analysis realising that he is firmly set in his ways.
Heck, he won't even try our a computor and probably doesn't
have a new fangled television

When quotes are used, I get 455. Without quotes, I get about 297,000.
Since I am looking for the exact expression, not just the three words
somewhere in a web page, I use the quotes.

I am using Firefox with plain 'ol Google. No special setups.

In any case, you answered my question. "Wave reflection model" means
nothing beyond ordinary electromagnetic theory. Big deal.

Hello,

I think OFDM SFN is not applicable to your frequency band. In addition
they speak about decorrelation. With "distance" between antenna
elements of about 5ns, received signals in FM BC band on your single
antenna with 2 elements are fully correlated.

About 3 dB gain increaser over single HW dipole; OK.

Best regards,

Wim

Cecil Moore wrote:
"What am I missing?"

Radio waves spread during propagation. Huygens` principle is a cause.

Huygens says:
Each point on a primary wave front can be considered as a new source of a secondary spherical wave and that a secondary spherical wave front can be constructed as the envelope of these secondary waves. This is illustrated in Fig. 5-37 on page 144 of the 3rd edition of Kraus` "Antennas".

Jouko,
I had the same problem, despite assurances from the wholesaler in the USA where I bought the the two Hamsticks, they were resonant at their lowest at 3750 kHz. I needed to operate them at a lower frequency of no more than 3650 kHz

I tried extending the stainless steel "stinger" but I couldn't find anything long enough.

Then I tried a disk of aluminium 1.6mm x 75 mm in diameter, fitted between the stainless whip and the antenna proper, and that reduced the resonanant frequency to 3575 kHz, adjusting the stinger length was necessary of course.

You may have to make the diameter of the disk slightly larger to get it to resonate at the lower frequency, just a matter of cut and try.

Using my MFJ Analyser, the feedpoint resistance was close to 50 ohms.

It was a very simple fix!

Just a slight addition here. Before lasers, the way to get a
coherent light source was to bottle-up a high-intensity,
monochromatic source, such as the aforementioned sodium-
vapor light, in a reflective cavity with a very small pinhole in
its side. As the photons dribble out through the pinhole, they
are forced into a somewhat phase-coherent wave train. This
source was used in optical processors for synthetic-aperture
imagery back in the 50's.... Jim, K7JEB

Ok, the antenna is portable. Toss a wire over a couple of tree limbs
and either use full-sized 80 meter dipole, or load it with loading
coils. If you load the antenna with coils located at the end point of
40 meters, you may find yourself with a dual band antenna -- 40/80.
Since you are operating primarily local 80 meter operation, any height
above ground up to about 20 feet will result in NVIS, pretty good
signal there.

You could also try a tree-limb somewhat vertical. Drop a short ground
rod into the ground, tap shield to that and toss other end of 65 foot
wire (plus or minus) over a tree limb. It will operate, but not
perfect. However, it should work as well or better than the
hamsticks.

Just another thot

John,

Yes I think using capasitive loading at the end of coil parts is the right
way to move the frequency.
What kind of results did you get with the hamstick dipole?
OK 50Ohm feedpoint resistance. I thought it is lower, but maybe it is so
due to high loss resistance in coils.

Instead of writing two lines identifying the element
and providing the function describing its energy flow,
you write 14 lines tell me I should do it.

But my explanations do not require this element to
store and return the "interference energy".

You should consider that perhaps your inability to
identify the element and its energy function really
calls into question your concept of "interference
energy" being stored and returned later.

> equal zero.

When energy is transferred, the quantity is decreasing
in the supplier and increasing in the receiver. From
the supplier's perspective, this is a negative flow and
from the receiver's perspective, a positive flow.

In calculus terms, energy flow is the derivative of the
quantity of energy, i.e. the rate of change of the
amount of energy. The slope of the curve recording the
amount of energy can be negative, even though the amount
of energy is always positive.

No. "cos(theta)" only appears in the equations describing
the average, and not in those equations that describe the
actual function of time.

I suppose, if you want to rename superposition as interference.
But none of my basic circuit theory books use the word
interference when discussing superposition.

> > Because the powers imputed to the
> > constituent voltages of superposition do not represent

>
> That statement is a violation of the wave reflection
> model. Do you really believe that when you look
> yourself in the mirror that those reflections are

> devoid of energy? If so, please feel free to prove
> your assertion.

If the powers imputed to the constituent voltages of
superposition did represent actual energy flows, then
you would be able to simply add them to get the total
flow, since energy can not be created or destroyed.

The fact that a correction needs to be applied when
adding them is proof that they can not be actual energy
flows.

But you know that, and that is why you have to search
for where this correction, that which you call the
"interference energy", goes. Because only if you can
account for it, can you claim that it is an actual
energy flow, which is needed to make you explanations
agree with conservation of energy. But in this example
you can not account for this "interference energy".
You have not identified the element that stores it nor
being able to obtain a function which describes the flow
into that element. You should take this as a reason to
call into question the whole idea that this "interference
energy" is an actual energy flow.

> > But you have to be cautious that you are applying

If *your* "wave reflection model" includes the idea that
Pref always represents an actual energy flow, then *your*
"wave reflection model" is wrong.

> > Or perhaps, these powers of which you speak do not

> that makes your argument not with me, but with Ramo,
> Whinnery, Johnson, Chipman, Slater, Hecht, and Walter
> Maxwell. Good luck on winning that one.

I am not convinced. It is clear that *your* "wave reflection
model" is wrong, but I have not seen these other authors
invest any effort in trying to explain where the reflected
power goes. Perhaps they realized it was a meaningless

question and their "wave reflection models" do not require
that the Pref represent an actual energy flow.

> > The difficulty of accounting for these powers is entirely

>
> Ignoring the role of interference and lumping all the
> energy components into a mashed potato salad is one
> method of sweeping everything under the rug so you
> can ignore the problem instead of solving it.

I am still waiting for the simple answer as to which
element stores and returns this "interference energy" and
the function that describes the flow into this element.

> > Or possibly, the premise that these powers represent
> > actual energy flows is flawed.
>
> Feel free to prove the wave reflection model wrong.

That your "wave reflection model" is inconsistent with
conservation of energy (until you identify the storage
element and its energy transfer function) should be proof
enough.

> > This turns out, however, just to be an ideosyncracy of the math,
> > much like the way Pf-Pr is the actual energy flow in the transmission
> > line because of the way that Vf and Vr are derived from Vactual
>
> Feel free to prove the math wrong.

The math is correct. It is the interpretation that is in error.

Pf-Pr is always equal to Pnet simply because of the way that Vfor
and Vref are computed. Even though Pf-Pr adds to the actual measured
energy flow, it does not mean that Pf and Pr are actual energy flows.
They MUST add simply becase of the way they are computed.

The same is true for some of the "proofs" in your other papers. The
successful equalities are simply a consequence of the way the numbers
being added are computed. A successful equality does not necessarily
prove an interpretation.

> > It would be good, if just for a day, you let go of the
> > idea that Preflected represents an actual energy flow.
>
> I will do that the day that you prove those reflections
> from your mirror, that allow you to see yourself each
> morning, contain zero energy.

This is indeed the root of the problem. You need to let go of the mirror just long enough to get over the hump. As it stands, whenever you approach the hump, you think about the mirror and refuse to see what might be on the other side of the hump. That is why I suggest letting go of the mirror just for a short while. Explore to see if there exists a completely self consistent set of explanations on the other side of the hump. You will find it to be so. But this can only happen if you let go of the mirror long enough to get over the hump.

If it doesn't work out, you can always pick up the mirror again. There is nothing to lose by temporarily doing some exploration without the mirror.

> if [V1(t)^2 + V2(t)^2] NOT= [V1(t) + V2(t)]^2, then
> interference is present. Did you miss Physics 201?

Let us build a slightly better example that complies with
your "NOT =" expression above.

```
+-----------------------------------+
| |
Vs1(t) = 141.4cos(wt) \
| = 100 Vrms Rload /
| 50 ohms \
Vs2(t) = 70.7cos(wt) /
| = 50 Vrms |
+-----------------------------------+
```

Using superposition the contribution from source 1 is
Vload.s1 = 100 Vrms
Iload.s1 = 2 Arms
and from source 2 is
Vload.s2 = 50 Vrms
Iload.s2 = 1 Arms
combining
Vload = 150 Vrms
Iload = 3 Arms

From
Pload = Vload * Iload
= 150 * 3
= 450 Waverage

As can be seen, this example satisfies your requirement
for interference:
[V1(t)^2 + V2(t)^2] NOT= [V1(t) + V2(t)]^2

Computing the imputed powers for the waves from each source
we have
Pload.s1 = 100 * 2
= 200 Waverage

Pload.s2 = 50 * 1
= 50 Waverage
To obtain the power in the load from these imputed powers
we need to use
Pload = Pload.s1 + Pload.s2 + Pload.correction
450 = 200 + 50 + Pload.correction
200 = Pload.correction

From previous analysis
Pcorrection = 2 * sqrt(P1 * P2)cos(theta)
(the cos(theta) term is appropriate here because these
are average powers being used)
Pcorrection = 2 * sqrt(10000) * 1
= 200
as required from above.

So according to your energy analsysis, the power in
the load comes from
the wave from source 1 = 200 W
the wave from source 2 = 50 W
"interference energy" = 200 W
for a total of
450 W as required.

Now if the 200 W from the wave from source 1 and the
50 W from the wave from source 2 represent actual
energy flows, then the "interference energy" must
also be an actual energy flow to satisfy conservation
of energy.

What element provides the energy for this "interference
energy" flow? Note that in this analysis, this energy
is an average energy flow, so it can not be saved during
part of the cycle and returned during another part.

In other posts, you have suggested that this would be
a constructive interference energy and that there would
be an equal destructive interference energy to provide
it. If you still claim this, where is this destructive
interference happening?

JN wrote:
> - Adding center extenders could help but then 75m hamsticks are out of 80m
> band ... Any comments on these?

This is not necessarily true. Since the length of
the top stinger has a much greater effect on resonant
frequency than the length of the bottom section, you
can increase that bottom section length by a large
amount and then adjust the top stinger length by a
smaller amount to achieve the desired resonant
frequency. And you are going down in frequency to
the CW portion of 80m.

For instance, you might extend the bottom portion
by 6 feet and only have to shorten the top stinger
by 2 feet. (When you shorten the stinger, you may
have to hacksaw off a portion to keep the stinger
bottom from residing in the middle of the loading
coil.)

Let's say you have an eight foot long base-loaded
mobile antenna. You decide to move the loading coil
farther up the antenna to the center-loaded position.
If you keep the *same length and same coil*, the resonant
frequency will increase. You have to add more stinger
length to bring it back to the original resonant
frequency (or more coil). Moving the fixed coil farther
away from the feedpoint requires the antenna length to
be increased. That fact works in your favor.

Since the additional bottom section is moving the
fixed loading coil farther away from the feedpoint,
the above effect will occur for your extended
configuration. Experiment with it and see what
happens. You could just use wire for the
experimentation and hang it between two supports.

```
-----/////-----+-----FP-----+-----/////-----
hamstick wire wire hamstick
```

Hustler makes various extender sections. I have
2 foot and 5 foot sections from Hustler.

Most of my extender sections are from Henry, the
Texas Bugcatcher guy. They are the "BASE MAST"
sections available in lengths from 1/2 foot to
5 feet and special lengths can be ordered.

I'm just trying to understand what Terman said.
Did he say that all of the radiation is perpendicular
to the radiating element or that most of the
radiation is perpendicular to the radiating element
or that none of the radiation is off the ends
of the element?

It is a big deal when someone asserts that there is
no energy in a reflected EM wave or that the energy
in a reflected EM wave doesn't have to be conserved
or that a reflected wave doesn't obey the rules
of the wave reflection model.

But the Method Of Moments used by NEC for antenna radiation patterns calculates the interference at a point in space based on radiation from different elementary dipole sections of the antenna. For instance, when the antenna is two wavelengths long there is no more broadside radiation than there is radiation off the ends.

In "Antenna Theory" by Balanis, in Chapter 8, page 407, on Moment Method, he illustrates the method using radiation angles less than 45 degrees to the radiating element.

I have previously multiple times identified the element
as the network reactance and pointed you to a reference.

If you were asking me to teach you the English
language on r.r.a.a, you would get the same response.

> I suppose, if you want to rename superposition as interference.
> But none of my basic circuit theory books use the word
> interference when discussing superposition.

I'm not renaming superposition. I'm using the
definition of "interference" provided by Hecht
in "Optics". Superposition can occur with or
without interference. The present discussion is
about superposition with interference present.
Interference is just a word which identifies
the special case of superposition that is
under discussion.

> If the powers imputed to the constituent voltages of
> superposition did represent actual energy flows, then
> you would be able to simply add them to get the total
> flow, since energy can not be created or destroyed.

There you go again, confusing power and energy.
There is *NO* conservation of power principle.
Until you give up on superposing powers, you
are doomed to failure. There is absolutely nothing
wrong with storing energy and turning it into
power later in time. Do you think that backup
storage batteries are a violation of the
conservation of energy principle?

> The fact that a correction needs to be applied when
> adding them is proof that they can not be actual energy
> flows.

There is *NO CORRECTION TO THE ENERGY COMPONENTS*. There
is only a correction to the power components to account
for the time the energy is being stored before it is
dissipated. You really need to learn the difference

between energy and power.

> You should take this as a reason to
> call into question the whole idea that this "interference
> energy" is an actual energy flow.

Your argument is not with me - it is with experts
like Eugene Hecht. Please read his *57 page* Chapter
9 on "Interference" and then get back to us. With 57
pages devoted to the subject, Hecht doesn't seem to
share your problems with it.

> If *your* "wave reflection model" includes the idea that
> Pref always represents an actual energy flow, then *your*
> "wave reflection model" is wrong.

When you can prove that reflected traveling waves contain
zero energy, i.e. that ExH=0, I will accept your assertion
but not before. Exactly how does a TDR detect zero energy?

In fact, the thing you need to do is forget the transmission
line and deal with light waves encountering boundaries with
different indexes of refraction. The problem is identical,
but dealing with light out in the open prohibits you from
pushing your mashed-potatoes energy religion.

Already answered a few postings ago. Sorry you
missed it. Here it is again:

Here are the basic principles:

When destructive interference occurs, there is "extra"
energy left over from that isolated event. That energy
must go somewhere. Here are the possibilities in a
typical lossless RF transmitting system.

1. The source can throttle back on its energy output
to compensate for the destructive interference energy.

2. Reactive components can store the destructive
interference energy and return it to the network at
a later time.

3. In the absence of (1) and (2) above, an RF energy
wave is launched in a direction that allows the
"extra" energy to leave the destructive event area.

When constructive interference occurs, there is "missing"
energy needed to be supplied into that isolated event. That
energy must come from somewhere. Here are the possibilities
in a typical lossless RF transmitting system.

1. The source can simply supply the energy needed by
the constructive interference event.

2. Reactive components can return stored energy to
the network.

3. In the absence of (1) and (2) above, constructive
interference energy *must* be supplied in real time
by destructive interference between two other waves.

Completely logical and it works. Interference or vector sum?

Terman illustrates radiation from an elementary doublet (dipole) , and it is mostly at right angles to the antenna axis, on page 865 of his 1955 opus. On page 866 he shows an actual antenna consisting of numerous elementary doublets and on page 867 he says:
"The result is that the fields radiated from different elementary sections of a long wire add vectorially to give a sum that depends on direction."

Kraus devotes Chapter 14 in the 3rd edition of "Antennas" to: "The Cylindrical Antenna and the Moment Method (MM)."

Best regards, Richard Harrison, KB5WZI

One other observation: Although the interference model
will work for a lumped circuit example, there is no
reason to use it as it complicates the computations
and adds nothing to the solution. The wave reflection
model also works for circuits but there is simply no
good reason to use it for lumped circuit analysis.

Where interference becomes a useful tool is when it
happens away from any compensating source. An analysis
of the interference of two EM light waves in free space
far removed from any source leaves us with two constant
sources of energy, the total energy of which has to go
somewhere. The following two web pages tell us exactly
where the energy goes.

http://www.mellesgriot.com/products/optics/oc_2_1.htm

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

Your theory seems to require that the EM waves must
know beforehand whether to carry energy or not from
a star light years away. You apparently have invented
a rather curious "smart wave theory".

The question is: How did those two interfering waves
from Alpha Centauri know whether to arrive at the
planet Earth ten years later carrying ExH energy
or not carrying ExH energy?

If you use a fiberglass rod for the coil form similar
to the hamstick fiberglass rod and wind the same number
of turns of the same size wire on it, it should work.
But if you are going to go to that trouble, you might
as well wind high-Q coils.

In fact, if you replace the 75m hamstick coils with
large-diameter high-Q coils, you can probably increase
your radiated power by 1000%, i.e. 10 dB :-).

Your constant voltage sources are NOT a better example
and not even a good example. To confront the subject
being discussed, you should use constant power sources.

The reason is obvious. A constant steady-state EM
wave is a constant average power source, not a constant
voltage source. Constant voltage source examples
just won't do.

Try your example with constant power sources and
see what happens.

Indeed you have, but you have not answered the second clause
in the question. Until you can provide the energy flow
function of the element you claim is storing the energy
there is no reason to believe that it is the element.

Can it be that hard to provide the function?
Or perhaps the element you have identified does not have
the appropriate energy flow function? (It doesn't.)

Conservation of energy arises from the inability
to create or destroy energy. Energy can only flow from
one element to another.

This requires that the sum of the flows out of the
elements providing energy equals the sum of the flows
into the elements receiving the energy. Choose
whatever name you want for it, but this is the
reason that
Ps(t) must equal Prs(t) + Pg(t)

And it is just as powerful a concept as conservation
of energy since it follows directly from that principle.

> > The fact that a correction needs to be applied when

You see. There you go again. Refusing to set aside an
assumption, even temporarily. It does make it difficult
to explore alternate explanations if you stop before you
start.

> Exactly how does a TDR detect zero energy?

Does it detect energy? Are you sure?
Or is it voltage that it detects? Or current?

> In fact, the thing you need to do is forget the transmission
> line and deal with light waves encountering boundaries with

No. Light, in a 3 dimensional space and at such high frequency makes the math and measurements so complicated that it is extremely difficult to follow the energy. Much better to learn from a one-dimensional transmission line and then see if the solutions also apply to light. Which they do. But the analysis is tractable in a transmission line.

It is unfortunate that they did not expect someone to use
their website to try to understand the behavior of transmission
lines, or they might have taken more care to explain what is
happening at the sub-wavelength level.

> Your theory seems to require that the EM waves must
> know beforehand whether to carry energy or not from

That would be nice, but no, not required. Though it is
easy to see how one might be misguided into thinking so.

The question is, can you set aside the mis-guiding
influences long enough to learn about the alternative
explanations?

> The question is: How did those two interfering waves
> from Alpha Centauri know whether to arrive at the
> planet Earth ten years later carrying ExH energy
> or not carrying ExH energy?

It is a question, but only seems relevent if *your* model
is incorrect.

> being discussed, you should use constant power sources.

Well, if that is all it takes to stop you, here is a
variation that should satisfy. It aligns well with your
example of Fig 1-1......

Let us build a slightly better example that complies with
your "NOT =" expression above.

```
50 ohms 50 ohms
+------/\/\/\----------------+---/\/\/\---+
| | |
| \ |
Vs1(t) = 282.8cos(wt) Rload / Vs2(t) = 141.4cos(wt)
| = 200 Vrms 50 ohms \ | = 100 Vrms
| / |
| | |
+---------------------------+------------+
```

Using superposition the contribution from source 1 is
Vload.s1 = 100 Vrms
Iload.s1 = 2 Arms
and from source 2 is
Vload.s2 = 50 Vrms
Iload.s2 = 1 Arms
combining
Vload = 150 Vrms
Iload = 3 Arms

From
Pload = Vload * Iload
= 150 * 3
= 450 Waverage

As can be seen, this example satisfies your requirement
for interference:
[V1(t)^2 + V2(t)^2] NOT= [V1(t) + V2(t)]^2

Computing the imputed powers for the waves from each source
we have
Pload.s1 = 100 * 2
= 200 Waverage
Pload.s2 = 50 * 1
= 50 Waverage
To obtain the power in the load from these imputed powers
we need to use
Pload = Pload.s1 + Pload.s2 + Pload.correction
450 = 200 + 50 + Pload.correction
200 = Pload.correction

From previous analysis
Pcorrection = 2 * sqrt(P1 * P2)cos(theta)
(the cos(theta) term is appropriate here because these
are average powers being used)
Pcorrection = 2 * sqrt(10000) * 1
= 200
as required from above.

So according to your energy analsysis, the power in
the load comes from
the wave from source 1 = 200 W
the wave from source 2 = 50 W
"interference energy" = 200 W
for a total of
450 W as required.

Now if the 200 W from the wave from source 1 and the
50 W from the wave from source 2 represent actual
energy flows, then the "interference energy" must
also be an actual energy flow to satisfy conservation
of energy.

What element provides the energy for this "interference
energy" flow?

In other posts, you have suggested that this would be
a constructive interference energy and that there would
be an equal destructive interference energy to provide
it. If you still claim this, where is this destructive
interference happening?

...Keith

True for energy. Not true for power.

> And we are still waiting for the energy flow function
> for the element that you claim is doing the storing
> of the energy.

If you cannot understand the reference I gave you,
I don't know what to tell you.

> Does it detect energy? Are you sure?
> Or is it voltage that it detects? Or current?

Please provide proof that voltage or current can
exist without energy.

I have said a source can match any destructive interference
by supplying less power and match any constructive interference
by supplying more power. If you have to falsify what I have
said to try to win the argument, you have already lost.
Since you have ample sources available in your example, my
assertion about interference far removed from any source
doesn't apply - but you know that.

Monochromatic is not the same as coherent or in phase such as a
laser.

I have a hustler 3 footer I use all the time..
Really cranks the performance up when you are
parked and can use a taller whip.
My normal whip is 11 ft, exactly center loaded,
and the mast makes it 14, with the coil at 8 ft.
I wish I had a 5 foot version. Might have to get
one of those for industrial strength use. :/
Of course, if I had another 5 ft mast, I'd end up
coupling them together and having 8 ft. :)
There is no such thing as overkill with a
stationary mobile setup. lol
An 8 ft mast would give me a total height of
19 ft, and the coil would be at 13 ft.
That would brown the food on 75/40 m... :-

The bottom line in a nutshell? I'll try.

First, I added a note to both spreadsheets indicating that zero degrees is CURRENT zero degrees. This because the source turns out to be reactive, with current peak 45 degrees from voltage peak.

> http://www.fairpoint.net/~rsparks/Smooth%20Power%20Reflection.pdf

The spreadsheet addresses the following issues:

Does the traveling wave carry power? Yes. The spreadsheet was built assuming that power is carried by traveling waves. Because the resulting wave form and powers seem correct, the underlaying assumption seems correct.

Is power conserved on the transmission line, meaning, can the energy contained in power be conserved and located over time on the transmission line? Yes, the spreadsheet was built assuming that power could be conserved and traced over time so the underlaying assumption seems correct.

Does interference occur in this example? The spreadsheet was built assuming that voltage and currents from superpose in a manner consistent with constructive and destructive interference, so the underlaying assumption seems correct.

Is power stored in the reactive component for release in later in the cycle or during the next half cycle? Yes, power is stored on the transmission line during the time it takes for power to enter the line, travel to the end and return. The time of wave travel on the transmission line is related to the value of the reactive component.

Does the direction of wave travel affect the measurement of voltage and the application of power to a device? Yes. A wave loses energy (and therefore voltage) as it travels through a resistance. As a result, power from the prime source is ALWAYS applied across the sum of the resistance from the resistor AND transmission line. The spreadsheet was built using this assumption and seems correct. (At times during the cycle, the forward and reflected waves oppose, resulting in very little current through the resistor. During those times, the power applied to the transmission line is much HIGHER because the reflected wave reflects

from the load and source, and merges/adds to the forward wave from the source.)

Is the power interference equation Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(theta) valid? The equation was not reviewed on this spreadsheet.

The bottom line, but maybe not in a nutshell.

3661. Re: Hamstick dipole for 80m

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-27 08:43:49 UTC
From: JN <jnxx@vfemail.net>
Message-ID: <47eb5995$0$23816$9b536df3@news.fv.fi>
Source record: 26733

I made an interesting simulation for the ham stick dipole.

I first took total lenght 16 FT (2x hamstick), at 4MHz loading coils near
feedpoint calculated to be abt. 60 mikroH
Then I took total lenght 28 FT (8+6/FP/6+8) coils then moved to almost
center of elements. at 4MHz calculated 56 mikroH
and the same configuration at 3.56 MHz calculated 71MikroH for each coil.

Now 75m hamsicks seem to have abt. 60mikroH coils.
If you use 2x6Ft extenders at center you need 71 mikroH to resonate at
3.56Mhz.

This simulation uses lumped coils not helical like in hamstick, but I think
it is possible to use 75m sticks with extenders and still you need to lower
the resonance for 80m CW use.

> Monochromatic is not the same as coherent or in phase such as a
> laser.

Just a slight addition here. Before lasers, the way to get a
coherent light source was to bottle-up a high-intensity,
monochromatic source, such as the aforementioned sodium-
vapor light, in a reflective cavity with a very small pinhole in
its side. As the photons dribble out through the pinhole, they
are forced into a somewhat phase-coherent wave train. This
source was used in optical processors for synthetic-aperture
radar imagery back in the 50's....

May I suggest that you use the word "redistributed"
instead of "reflected" as does the FSU web page at:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

For the purposes of this discussion, I would suggest
that the word "reflection" be reserved for something
that happens to a single wave. When two waves are
superposed, energy can be redistributed but technically
it is not an ordinary reflection. I once used the
word "reflection" to describe both phenomena and it
confused people. Now I am careful to call the
reversal of energy flow due to superposition a
"redistribution" instead of a "reflection".

For instance, the multi-colored patterns seen when
a thin film of oil is on top of a puddle of water
is not an ordinary reflection but a combination
of multiple reflections and interference.

In addition, the reflection coefficient seen by the
reflected wave in our examples is 0.0 since the source
impedance equals the characteristic impedance of the
transmission line. There are no ordinary reflections
when the reflection coefficient is zero.

> > into the elements receiving the energy.
>
> True for energy. Not true for power.

Ummmmm. Conservation of energy requires that the total
quantity of energy in the system not change. This requires
that the sum of the changes of the quantity of energy in
each element be zero. A change in energy quantity is a
flow. The energy flows must sum to zero. Energy flow is
power. The powers must sum to 0 to satisfy conservation
of energy.

> > And we are still waiting for the energy flow function
> > for the element that you claim is doing the storing
> > of the energy.
>
> If you cannot understand the reference I gave you,
> I don't know what to tell you.

You could simply do the derivation for an example that
demonstrates your hypothesis.

> > Does it detect energy? Are you sure?
> > Or is it voltage that it detects? Or current?
>
> Please provide proof that voltage or current can
> exist without energy.

I realize now that you were probably thinking of a TDR
that sent a pulse (I was thinking of one that sent a
step). My assertion is that when
Ptotal = Pfor - Pref
the idea that Pfor and Pref describe actual energy
flows is very dubious. Ptotal always describes an

energy flow.

When Pfor is 0, then Pref is equal to Ptotal and since
Ptotal is always describing an energy flow, Pref does
in this case as well. Similarly when Pref is 0.

And now, since you are having trouble computing the
energy flows into the various elements here they are
again, for the circuit in the example of Fig 1-1, 100 Vrms
sinusoidal source, 50 ohm source resistor, 45 degrees of
50 ohm line, 12.5 ohm load, after the reflection returns...

The power flow into the line is
Pg(t) = 32 + 68cos(2wt)
and along with
Ps(t) = 100 + 116.6190379cos(2wt-30.96375653)
Prs(t) = 68 + 68cos(2wt-61.92751306)
energy is nicely conserved because
Ps(t) = Prs(t) + Pg(t)

The load presented by the line has a resistive and a
reactive component, so we can separate the power into
two parts
Pg.resis(t) = 32 + 32cos(2wt-61.92751306)
Pg.react(t) = 0 + 60cos(2wt+28.07248694)
which, for confirmation, nicely sums to Pg(t) above.

Now as I recall, your claim was that the total power
dissipated in the source resistor would be the power
dissipated before the reflection returned plus the
power imputed to be in the reflected wave plus the
power stored in and returned from some other element
in the circuit.
Prs(t) = 50 + 50cos(2wt)
+ Pr.g(t)
+ Pstorage
= 50 + 50cos(2wt)
+ 18 - 18cos(2wt)
+ Pstorage
Pstorage = 68 + 68cos(2wt-61.92751306)
- 50 - 50cos(2wt)
- 18 + 18cos(2wt)
= 0 + 36cos(2wt-90)
which is not the power function of the reactive
component of the line input impedance, Pg.reac(t),
computed above. So the energy is not being stored
in the reactive component of the line input
impedance.

I had not realized that you had these alternate sources for
the interference energies, not having seen that in your papers.

But it is one way to sidestep the issue; different rules for
the expectations of superposition and interference in different
scenarios.

I am surprised then, for the example of Fig 1-1 with 12.5 ohms,
that you don't just say "There is a source nearby, that *must*
be where the unaccounted energy comes from", and leave it at
that.

Clip

I think "redistributed" would be the word if the discontinuity included a resistance. "Reflection" is the historical word for wave reversal and implies a "mirror image", which is not the same as the forward image.

I hope the surgery does not take you away from the discussion for long.

How do you adjust the coil at that height? Of course I find that I
choose and spend most of my time on one band per mobile session, so
maybe it isn't a big problem.

Hi "UMC"
Is it practical to mount the antenna outside toe helicopter? I once designed an antenna system for military helicopter VHF homing. I used two dipoles made of foil taped to the plastic windshield. It worked. The idea was/is simple, but you'd need to build a seperate electronic device to go between the antenna and the receiver. And, you'd (of course) need to manuver the helicopter rather than twist/turn the antenna, because, the helicopter would be the antenna.

Keith Dysart wrote:
> So you are having difficulty doing the math to justify
> your hypothesis.

Actually no, the math is not difficult. I'm pre-
occupied with something else and think it's just
time to agree with Hecht that instantaneous power
is "of limited utility".

Have you taken a look at Roger's spreadsheets?

> Conservation of energy requires that the total
> quantity of energy in the system not change.

:-) Isn't the whole purpose of a transmitting
antenna to radiate energy away from the antenna
system? And that radiation continues to be "lost"
from the system space for some time after the
source power is removed?

Wouldn't you have to define the "system" as the
entire universe for your statement to be true?

> The powers must sum to 0 to satisfy conservation
> of energy.

That may be true, but there's still no conservation
of instantaneous power principle. A hot resistor
continues to radiate heat long after any power
source is removed.

> You could simply do the derivation for an example that
> demonstrates your hypothesis.

Already done on my web page. My only actual hypothesis
concerns average power. I've wasted too much time
bantering about something that Hecht says is "of
limited utility".

> the idea that Pfor and Pref describe actual energy
> flows is very dubious.

Again, look yourself in the mirror and tell yourself
that what you are seeing contains no energy. The
theory that some EM waves contain energy and some
do not is not new to you. Dr. Best was the first to
theorize that canceled waves continue to propagate
forever devoid of energy. Someone else asserted that

canceled waves never contained any energy to start
with. I strongly suspect that what you are seeing
in the mirror are the waves that didn't cancel and
that do contain energy. :-)

> So the energy is not being stored
> in the reactive component of the line input
> impedance.

Assuming you have not made an error, so what? Energy
stored in the reactance is only one of the possibilities
that I listed earlier. As I said in an earlier posting
which you declared a non-sequitor (sic), one or more of
the following is true:

1. The source adjusts to the energy requirements.

2. The reactance stores and delivers energy.

3. Wave energy is redistributed during superposition.

4. Something I haven't thought of.

The ExH reflected wave energy exists and cannot
be destroyed. It goes somewhere and its average
value is dissipated in the source resistor in
my special case example. You are attempting to
destroy the reflected wave energy using words
and math presumably knowing all along that
reflected wave energy cannot be destroyed.

Keith Dysart wrote:
> I had not realized that you had these alternate sources for
> the interference energies, not having seen that in your papers.

I only posted it three times here and you chose to
ignore all of those postings. I have published only
one paper with three more to go. The special case
Part 1 contains zero average interference so there
is no alternate source for average interference and
indeed, none is needed for Part 1.

> But it is one way to sidestep the issue; different rules for
> the expectations of superposition and interference in different
> scenarios.

That's why I have four parts only one of which has
been published. The rules are not different but the
conditions within the examples are different. Part 2
will be an example with the condition of average
destructive interference existing at the source
resistor. Although there are no ordinary reflections
because the reflection coefficient is 0.0, there will
exist something that looks a lot like a reflection
caused by superposition/interference. The FSU web page
calls it a "redistribution", not a "reflection".
I am satisfied with FSU's word "redistribution" for
the results of coherent wave interaction.

> I am surprised then, for the example of Fig 1-1 with 12.5 ohms,
> that you don't just say "There is a source nearby, that *must*
> be where the unaccounted energy comes from", and leave it at
> that.

Since my special case example contains zero average
interference, the average power output of the source
is constant and unaffected by zero interference.
There is zero average energy unaccounted for.

Part 2 will illustrate the source adjusting its power
output to compensate for destructive interference.

> as the forward image.

What I am suggesting is that "redistribution" be used
instead of "reflection" for cases where there exists
no discontinuity. If the source resistor matches the
Z0 of the feedline, there is no discontinuity and
therefore no conventional reflection, yet there are
cases where reflected energy is redistributed back
toward the load. That reversal appears to be a reflection
but is actually the result of superposition along
with destructive interference between *two* waves.
That is what causes the disparity between the physical
reflection coefficient, (Z1-Z2)/(Z1+Z2), and the virtual
reflection coefficient, SQRT(Pref/Pfor).

> I hope the surgery does not take you away from the discussion

This is sad.

But I suppose that if you are going to invent new science you might as well invent new terminology as well. 8-)

Yes, I know that the now-famous FSU web page uses "redistribution". Did you happen to notice that the page was created by a lab tech and a Java programmer? Do you suppose Hecht, Born and Wolf, and all of the other acknowledged experts would support dumping "reflection"?

Well, I only have a few taps on the coil, so I don't have to change
all that often. I might have three taps for 80m, a couple for 40m,
one each for the rest of the bands..
I'll tune the antenna in the normal 11 ft mode, using the usual
tap for the freq I'm using, and then I add the 3 ft mast.
I'll stay on the same coil tap, but shorten the stinger a couple
of inches or so.
I'm on 80 or 40 most all the time, so I don't have to change
but maybe twice a day.. 40 all day, and then I'll switch to
75 at night when it gets dark.

I would guess the answer is "yes" when the physical
reflection coefficient is zero - in order to avoid
a logical contradiction.

How does a "reflection" occur when the physical reflection
coefficient is zero, in violation of the wave reflection
model? Why is there often a difference between the
physical reflection coefficient and the virtual
reflection coefficient? Which one is wrong?

The convention that I have adopted is that the word
"reflection" is reserved for single wave events.

For multiple wave events where interference exists,
something besides a simple "reflection" takes place.
The intricate color patterns on the surface of a thin
film of oil floating on a puddle of water are not
simple reflections but instead an interaction of
multiple reflected waves. The resulting image bears
absolutely no resemblance to the incident image.

Following the FSU web page usage, the word "redistribution"
is used for multiple wave interaction events like wave
cancellation. (The words we choose to use to describe the
phenomena have zero effect on the phenomena.)

"A rose by any other name would smell as sweet."

Can someone explain this de-correlation to me? Is this not the same as a
phase shift? Would there not be a de-correlation when moving from broadside
to end fire?

Thanks for any assistance,
John

3681. FS: Open form coils

I have the following new open form coils for sale.

Air Dux coils

(3) 408T 1/2" dia X 2" long 8t/in $4 each
(4) 416T 1/2" dia X 2" long 15t/in $4 each
(3) 432T 1/2" dia X 2" long 30t/in $4 each
(4) 804T 1" dia X 3" long 4t/in $5 each
(3) 810T 1" dia X 3" long 10t/in $5 each
(3) 816T 1" dia X 3" long 16t/in $5 each

B & W coils

(1) 3006 5/8" dia X 1 1/4" long 8t/in $3
(1) 3008 5/8" dia X 1 7/8" long 32t/in $4

B & W xmitting coils each with a coupling loop on a 5 pin ceramic base
(You have to be old to remember these. :-))

(1) 10JEL (used) $8
(1) 40JEL $9
(1) 80JEL $10

Unknown manufacturer coils (but made like Air Dux)

(4) 1 1/4" dia X 10" long 6t/in $18 each
(2) 1 1/4" dia X 10" long 10t/in $18 each
(1) 2" dia X 10" long 4t/in $18
(1) 2" dia X 5" long 10t/in $9
(1) 2" dia X 7/8" long 10t/in $2

Lot price totals $261. I will discount if you buy the whole lot.

Prices are plus shipping in CONUS. I need your zip code to figure
shipping.

They're talking about that the received signals from the two antennas
are decorrelated, generally, with respect to the multipath. For the two
direct paths, it is just a time delay difference. But when you throw
reflections into the mix, they'll be decorrelated.

Virtually all DTV receivers use some form of adaptive RAKE receiver to
effectively utilize the energy in the multipath and to provide
resistance to multipath fading. To the receiver, adding another
transmitter just looks like another reflected path.

Would there not be a de-correlation when moving from
> broadside to end fire?

Depends.. How far did the phase center move when moving from broadside
to end fire.

Hi Jouko,

I made up a 4 band "spider" mount, to which you can screw in 4 sets of hamsticks. I have a full set of hamstick whips from 80m down to 6m.

So I have a multiband hamstick dipole array!

When one thinks about the feedpoint impedance, even without the capacitive disk, it certainly should be lower, but as I am using them at 7 metres from groundlevel in a portable situation, I use a small antenna tuner.

At that height, they act like a "cloud warmer" or a NVIS antenna, so at 80m its good for up to 350km. I haven't really given the other frequencies a try yet.

Let me know I can email you with a few pics of my multiband "spider mount", as I have a small lathe and milling machine in my workshop, it wasn't hard to make.

The simulator at that web site does seem to have
its issues. Ask it to simulate 700 nm + 680 nm
at the same amplitude and see if the result
represents reality.

...Keith

PS. The result should look like a 689.8 nm sine
wave of continuously varying amplitude.

Hi Jerry:

I guess if the helicopter was specifically part of the searching agency then you could do something like that. I'm not sure if they'd ever do that. The choppers and pilots are usually "on loan" from whatever agency is available to help when someone's lost. The CHP has some, most Sheriff's departments, Feds, Military, State Police, etc. When a person is lost, people seem to come out of the woodwork with the desire to help. That often includes agencies that own helicopters.

While I'm now a certified trainer because of my classroom time, I'm still a brand-newbie to search and rescue, and have never been on a "real" search for a missing person. I've located hidden transmitters on dozens of occasions, either hidden on a person who was part of the training, or just plain hidden. If I can get within a couple of miles of one of the transmitters I can normally go straight to it, even if it's down a drainpipe, under a bridge, or behind the coffee maker in a restaurant... it doesn't really matter much where it is located.

More of our training is related to understanding people with Alzheimer's and other forms of dementia than is related to actual radio work, and rightfully so. There's much to study on the human side of it. One of my greatest fears now is that I'll search for a person who is at a significant danger of being injured and is lost in a giant crowd of people, and they don't want to be found. I feel uncomfortable "pointing" the antenna around crowds of people for obvious social and psychological reasons. An example might be someone "lost" in Time's Square on New Years Eve.... the very thought shivers me timbers! :)

Luckily, being from Central California, I'll be much more likely to be searching orange groves than giant crowds. Interestingly, orange groves absorb a signal much more than I had thought they would, and, the signal propagates much better down the rows than across the rows. The trees were laden with oranges and I could barely hear a signal from one of our guys who was purposely trying to avoid us. He was literally 5 or 6 rows in (across) and I could hardly hear the signal. Once we got to the end of the grove and

got to look down the rows, the signal jumped.

Thanks again for all of your help!

Well, as it says ABOVE, “The transmit antennas need to be spatially separated by between 10 and 20 wavelengths...", so that must be how far.

The Hustler MO-1 and MO-2 masts have a hinge at 15" and 27" above the bottom
end: http://www.new-tronics.com/main/html/mobile__hf.html
They're 54" tall. The MO-3 is also 54" tall but doesn't have the hinge.
The MO-4 is 22" tall (no hinge).

In a short answer to your question, NO!

The finals won't burn out as there are none and you won't be feeding
radiation into your room.

However, as you probably noticed from the FM radio with the extendable
antenna, you sometimes get a better signal when you extend the antenna
nd move it to the right location.

A good (and matched) antenna may allow you to receive signals you
could not have received with a random length antenna.

Most radios that I have seen usually have a matching network built in
to match the antenna that comes with the radio. In most cases they
aren't that elaborate, just a small coil and a trimmer capacitor.

My father learned that as great as his 50 foot long copper wire worked
for listening to his favorite short wave broadcasts, the signals
improved immensely when I installed an fan-dipole for his three
favorite bands. Did he 'need' that antenna? no, he could hear his
stations without it, but the signal strength was improved and he was
able to pick up more stations.

Dad also ordered an antenna tuner kit, assembled it and attached it
to his 50 foot wire. He found a great improvement in signal strength

using the tuner, almost equal to the multi-band dipole I installed.

Signal to noise ratio are not synonymous with gain. One can have a lower-gain antenna with high s/n that outperforms a higher-gain antenna with low s/n. When it gets critical, the s/n can be the determining factor as to whether you receive intelligent communication or not.

You are probably digging for technical, theoretical information more than practical, but just in case...

If you look in stereo magazines, you seldom see radio ads bragging about how much better they receive than the competition. If you look in Ham magazines, that's a very important feature. Most consumers are looking for stereos that play music well and they listen to local stations. Most ham operators want to pull that weak signal out of the noise to make the contact.

Just some thoughts.

Hope this is helpful to someone.

Some one sent me an email and said these will do the job. Ceramic capacitor disk 10KV/1000pF. Do you think these would work?

This is my first attempt at making traps and I do not fully understand how they work. I am willing to learn as this is what makes the hobby great but I cannot find enough step by step info to lead me in the right direction.

Thanks

No. For an 80/40 meter trapped dipole, the traps will need a capacitor close to 60 pF. 1000 pF will not be suitable.

You might look at the traps made of coaxial cable where the inductance is tuned to resonance with the capacity of the cable length itself. No easier to construct, and heavier than the wire wound/capacitor trap, but eminently easier to obtain in the materials department.

Info available from Google.

I don't know about those particular ones. Some ceramic
capacitors are meant to be DC biased for bypass service.
I once tried to use disc ceramic caps across my ladder-
line. They caught on fire because they were not rated for
AC service and lit up the night sky.

Someone told me the ceramic insulator was actually
trying to physically vibrate at the RF frequency and
friction heated it up. I don't know if your capacitors
are rated for AC operation.

A friend of mine used silver mica capacitors for his
traps and they worked fine.

> This is my first attempt at making traps and I do not fully understand how

-------trap----------FP----------trap-------

An ideal trap is parallel resonant with a high Q. That
gives it a very high impedance at the resonant frequency
and acts somewhat like an open circuit at the resonant
frequency blocking the flow of current to the outer
parts of the dipole. At the resonant frequency, the
inductive reactance and capacitive reactance are equal.
A Grid Dip Meter will indicate the resonant frequency.

At 1/2 that resonant frequency, the inductive reactance
goes down and the capacitive reactance goes up so the
"trap" acts like a loading coil instead of an open
circuit on the lower frequency.

Traps can be made out of coax if you are interested.
The coiled outer shield provides the inductance and
the capacitance is provided by the center-wire-to-
shield capacitance.

Kraus talks about self-resonant traps with no physical
capacitors. The inter-winding capacitance of the coil
wire supplies the necessary capacitance.

Articles on capacitors for traps specify "transmitting"
type caps meaning high voltage ratings. I don't know
exactly the voltage rating required but it is in the
thousands of volts. That's why I used door-knob caps.

You can put capacitors in series to increase the
voltage rating but you also decrease the capacitance
and the voltages across each capacitor needs to be
equalized using resistors.

Hi Barrett,

A lot of this flies on the wings of presumptions. One, is that you
have an 80M dipole being trapped for 40M. If so, then two of them in
series for each trap will work just fine with an inductance of roughly
20 microhenries.

No, you don't need expensive 6KV caps unless you put the wrong
frequency to the antenna - and by wrong, I mean wrong band, not just
slightly up or down band.

The voltage across these traps (with all presumptions being observed)
will vary from 400V to 550V across the 40M band for an ideal antenna
in free space. You probably live on earth, so presumptions are
already beginning to shift.

Some ceramic capacitors have the value change with the instantaneous applied voltage. I know somebody who tried to use one in a tuned circuit - complete disaster. Do not use the ones that are meant for power supply bypassing.

If what you are trying to do is a dipole type antenna for 40m and 80m,
you do not need any capasitors at all. You can use choke-coils as in this
design
but leave the 20m and 15m dipoles out.

There are quite a few variables involved in determining how much voltage the traps will see, not the least of which is the L/C ratio of the trap. I dug out a model of a 40/20 meter trapped dipole using traps using RG-58 I did some time ago, and found the trap voltage to be 568 volts RMS with 100 watts at 14.0 MHz. That's 800 volts peak. A model of a 40/20 meter trapped dipole with trap component X = 1000 ohms at resonance and moderate inductor Q showed highest voltage of 648 RMS (over 900 volts peak) at 7 MHz. So I'd want to use capacitors with a 2 kV rating to provide some margin.

Not knowing where to get the right capacitors from and at a good price I am thinking more on the lines of making some coaxial traps for the time being and see how I get on. What put me off of the coaxial traps is the size. I did just find this article on another type of trap.
http://www.arrl.org/tis/info/pdf/9207035.pdf

It doesn't make it clear how you join the inner and outer coil together and if they are wound in the same or opposite direction. What do you think is the correct way to wind and join them are?

Is it possible to make all the traps on 40mm PVC pipe or do they have to be a certain size diameter for each band?

Thanks

NOT to mention, that at the HIGHER frequency, the trap is at
the HIGH VOLTAGE point of the antenna at that resonant frequency
! At 50 ohms, impedence, at the feedpoint , the Maximum Voltage for a
100 watt transmitterwould be 50 volts at 2 Amps, but at the HIGH volatge
points (1/4 wave each side of a dipole), there can be literally
THOUSANDS of volts, at (admittedly) very low current . And, caps are
rated at Breakdown Voltage! This is why (unless you use very low
power),that you need these high voltage Capacitors . Hope this helps
explain.

25.4 pf per ft - That's the capacitance of Belden 9907 RG-58a coax. I got
the info here:
http://www.trinetcn.com/images/spec_sheets/belden/bel9907.pdf
All cable manufacturers publish the capacitance per ft of their coax.
With that said, I've heard of folks using that property of coax along with
a form to wind their own traps using RG-58.
I would think that since we use coax all the time for transmitting, it may
be able to withstand the electrical stress of working as a cap.
Oh - here's an article on the idea: http://degood.org/coaxtrap/
and this one has color illustrations and a calculator :
http://www.seed-solutions.com/gregordy/Amateur%20Radio/Experimentation/CoaxTrap.htm

Message-ID: <Xns9A6FCC778E49EHuckleberrybigvalley@198.186.192.196>
Source record: 26638

If anyone here has experience with the Icom AH-4 antenna tuner, I have a simple question. Is there any reason I can not extend the control line beyond the 10 meter length that Icom supplies with a new tuner?

Just checking before I order one.

You can extend it, I have done so. If you extend it to ridiculous lengths,
or with thin wire, you can expect to mess up the ATU due to voltage drop in
the ground and +12 wires.

> kV rating to provide some margin.

I have done some mathematical modelling of so called coax traps with the bootstrap connection (or the Hi Z connection as used in ARRL pubs), and the work has halted needing some reconciliation with quality measurements of inductor Q and trap impedance. The problem relates to estimating the equivalent resistance in an inductor made from coax braid and covered in the PVC jacket.

I see W8JI reports measurement of a coax trap at 7Mhz with about 18k ohms at resonance, I have some data from DG1MFT who measured a trap around 7MHz on a R&S ZVRE VNA at somewhere around 22k ohms at resonance. I have measured some prototypes at over 15k ohms using the TAPR VNA, but it is not in the same class as quality instruments. In conclusion, I suspect that it is likely that coax traps have impedance well over 10k ohms at resonance.

One way to reduce the voltage impressed on the trap is to design the system so that the trap is not close to resonance at any operating frequency.

Such a design means moving beyond the simplistic explanation that such antennas depend on traps acting like an on/off switch at the resonant frequency, and that when they are resonant, the outboard conductors do not exist.

50 ohm cables with solid PE dielectric ALL exhibit a capacitance of about
30pF/ft. It is not a coincidence, C/unit length, Zo and velocity factor are
all related.

That method of estimating the capacitive reactance of an o/c stub (for that
is what you actually have) is only accurate for very short stubs.

Capacitors fabricated from coaxial transmission line are often much lossier
that quality fixed capacitors, so they should be used with care.

Hi Barrett,

I once fabricated just such a trap dipole. I started by cutting a dipole for 40m w/o traps.

You'll need to adjust the resonant frequency of the traps to the 40 meter band, so that the antenna wire on the outer ends of the traps is electrically "cut off". Physically, this is not very easy to do with fixed value components. I used stubs of coaxial cable as capacitors across the inductors, and tuned them by trimming the ends with wire cutters. Most coaxial cables exhibit a capacitance of about 30pF/ft, and I believe mine were around 18" long... about 45pF (498 ohms reactance at 7 MHz). At 7.1 MHz, an inductance of 11.15uH resonates with 45pF. Any combination of LC that yields resonance on 40m is acceptable but, the more L you have, the shorter the overall length will need to be in order to resonate on 80m. To a point, larger wire size and turn spacing for the inductor will yield better Q.

Unless you're running very high power, it really doesn't matter much what type of coax to use. The concern is voltage rating as, when operating on 40 meters, there will be higher voltage across the "capacitor". Larger diameter coax will have a greater voltage rating. Solid polyethylene coax will have a significantly higher rating than foamed polyethylene. From Belden...

Type: RG8/U
Part No: 8214
Dielectric: FPE (foamed polyethylene)
Max RMS: 300V
Capacitance: 26.0/ft

Type: RG8/U
Part No: 8237
Dielectric: PE (solid polyethylene)
Max RMS: 3700V
Capacitance: 29.5/ft

Type: RG58A/U
Part No: 8219
Dielectric: FPE (foamed polyethylene)
Max RMS: 300V
Capacitance: 26.5/ft

Type: RG58A/U
Part No: 8259
Dielectric: PE (solid polyethylene)
Max RMS: 1400V
Capacitance: 30.8/ft

Even using solid PE coax, I had issues with arcing over the ends of the stubs when running a kilowatt (it was OK with only 100W.) I alleviated that problem by trimming only the outer jacket and shield, leaving a short stub of center conductor and dielectric protruding. When done, seal the coax stub with non-corrosive RTV, etc.

I noticed that others made reference to the voltage rating of various capacitors. When AC is applied across a capacitor, a certain amount of current will flow thru it. Capacitors also have a rating in terms of current as well as voltage. While a TV doorknob capacitor has a voltage rating in tens of kilovolts, it won't handle much current. This is why you don't see them used (for example) as plate blocking capacitors in RF amplifiers, even though the DC voltage across them is much less than their rating. Where I work, we use lots of multilayer porcelain capacitors in industrial RF power sources (for CO2 lasers), mostly from American Technical Ceramics (http://www.atceramics.com/). Their datasheets list the current rating vs capacitance vs frequency.

One last question. Is the diameter of the traps at different frequencies
that important and why?

They tend to be larger towards top band.

Thanks

The ARRL Antenna Book says the above is the "amateur"
version of how traps work. :-) They say "commercial"
versions use non-resonant traps.

More inductance is required on the lower frequencies
as inductive reactance decreases with frequency.
Inductance increases with coil diameter. If the
choice is lots of coax for small diameter coils
vs a lesser amount of coax for larger diameter coils,
the latter is preferable because of lower losses.

I was not able to discern the derivation of the various equations
though the data in the columns looked somewhat reasonable. Were
the equation really based on the opening paragraph statement of
100 Vrms, or is it scaled to a different source voltage. The sin
functions have an amplituted of 100, which suggests a source of
200 volts or Vrms of 141.4 volts.

It was not obvious which columns were used to draw this correlation.

However, even if this experiment is consistent with the hypothesis
it only takes one experiment which is not to disprove the hypothesis.

I am not sure that I would describe this as the wave losing energy,
but rather as the voltage dividing between the two impedances.
If the source resistance was replaced by another transmission,
which could easily be set to provide a 50 ohm impedance, would
you still describe it as the wave losing energy?

I am not convinced. When there is very little current through the
resistor,
there is also very little current into the transmission line. This
suggests to me that the power applied to the transmission line is low.

> entire universe for your statement to be true?

Sort of, but there is an easy work-around. Since we
are not particularly interested in what happens to
the energy going to the source resistor, for
example, we define the boundary of the system to
pass through the resistor and simply account for
the energy as a flow out of the system. And we
do the same for the source since we are not
particularly interested in where the energy for
the source comes from; we just account for it as
a flow into the system. And lastly, we don't
really care where the energy on the line goes to
or comes from, so we just account for it as a flow
out of the system. You may have noticed that we
have removed all the components from the system,
it is a null system, and all we are doing is
accounting for the flows into and out of the
system. Hence
Ps(t) = Prs(t) + Pg(t)

> > The powers must sum to 0 to satisfy conservation
> > of energy.
>
> That may be true, but there's still no conservation
> of instantaneous power principle.

To conserve energy however, i.e. to have no energy
accumulate in the null system described above, the
flows must balance at all times, that is,
instantaneously.

> A hot resistor
> continues to radiate heat long after any power
> source is removed.

If you want to be that complicated you can; energy
is delivered instantaneously to the resistor according
to Vr*Ir (or equivalently, V**2/R), stored in the
resistor as heat and dissipated to the environment
later.

But for our purposes, we can stop that analysis at
the point where the energy enters the resistor and
use Vr(t) * Ir(t) to compute the instantaneous flow
into the resistor.

Unfortunately for your hypothesis, average power is
insufficient to account for energy which might be in
the reflected wave. An average power analysis agrees
with your hypothesis, while a more detailed instaneous
analysis disproves it.

If it was just a 'suspicion' you could probably let
go of the idea long enough to learn what is really
happening and why it is not inconsistent with the
idea that reflected wave energy is a dubious concept.

Your explanation is not complete until you can identify
the element that stores and returns the energy and its
energy transfer function.

Or not, as has been shown with the detailed analysis.

> You are attempting to

Energy can not be destroyed. This leads inexorably
to the conclusion that the reflected wave does not
necessarily contain energy.

Perhaps you should complete part one so that it fully
accounts for the energy flows before progressing to

writing part two. Average is not a full accounting.

You really need to read a text that systematically develops an understanding of the operation of a trapped antenna. It helps to understand the operation of an untrapped antenna.

Unfortunately, lots of articles in ham mags aren't very reliable, so you will need to read many articles and try to understand the underlying principles to filter out the misconceptions that find their way to publication.

By all means, ask questions about things you don't understand... but your questions seem more like guessing your way to a solution and plugging the gaps as they become apparent to you.

I simplified and changed the phase for the equation in column C from '100sin(wt-90) + 100sin(wt-180)' to '100sin(wt+90) + 100sin(-wt)' so that the total voltage in column D better matches with the voltages from my formula in column G.

The equation for column B is just the sine wave for the base wave, showing the voltage resulting to the source resistor from the peak current. The equation in column C is the same (from current) but recognizes that current from the reflected wave will cancel the current from the forward wave coming through Rs. The two waves are traveling in opposite directions so one angle must be labeled with a negative sign so that it will rotate in the opposite direction. In column C, the first term is the reflected wave and the second term is the base wave.

My formula, displayed in column G, uses the applied voltage of 141.4 volts. I thought it would be easier to see how the spreadsheet was built using current to find the voltages. You can see how the results of column D match well with those from column G.

Column E and column F display power. Column F recognizes that if 100 watts is applied continueously (on the average) over an entire 360 degree cycle, the final power applied over time would be 360 * 100 = 36000 watt-degrees. Part of the power comes from the reflection, part comes directly. Obviously, interference is very much at work in this example.

It should be OK to think of the voltage dividing between two impedances. The important thing is to consider how the reflected voltage sums with the forward voltage where it is measured. Because the two waves are traveling in opposite directions, the measured voltage is not the voltage applied to either Rs or the transmission line. This is why columns B and

C must be added to find the total voltage across Rs.

I don't follow you here. Right, power into the transmission line is low when the current in is low, and it is high when the current is high. It is clear that peak current and peak voltage do not occur at the same time except when measured across the resistor in column D.

>
> ...Keith
>

This is just one example, but it seems like the power is accounted for here. We need another example where power can NOT be accounted for.

Source record: 26554
Cross-posted to: rec.radio.amateur.antenna,sci.electronics.design,sci.electronics.basics

I did not see all the replies nor the original post but in the world of radio frequency (RF) match yes this would be an ideal situation since maximum energy transfer occur when Imepdance of the antenna (Zant) = Imedance of the Receiver Antenna Port (Zrx_port).

All this talk about noise while important to minimum detectable signal more greatly influenced by the internal Noise Figure (NF) of the receiver (RX). In my line of work, which is Radar engineering, we use a standard temperature T = 270 Kelvin to model the noise originating by natural extgernal sources of which the Sun is the biggest contributor.

The short end answer on HF you will probably not notice a big difference as long as the antenna is close between a 1/4 to 1/2 wavelength long [e.g. wavelength = Velocity of Light (C) / Frequency of Operation (Fo)]. However, if you use one of those collaspable whips found on the portable shortwave receivers you will. This is because the anyenna impedance is a lot less than the usual 50 Ohm impedance of the RX antenna port (e.g. Zant << Zrx_port).

You can match very short antennas with antenna tuners to make them transfer efficently to the RX antenna port but now the nasty parameter of effective antenna aperature (square feet or meters) reduces it caoture ability (think of catching a baseball with and without a glove, the probability of catching the ball is higher with a glove due to it larger capture area).

Well that is enough to put someone to ZZZzzzzzzzzz. Hi Hi

>
> My formula, displayed in column G, uses the applied voltage of 141.4 volts. I thought it would be easier to see how the spreadsheet was built using current to find the voltages. You can see how the results of column D match well with those from column G.

I am still having difficulty matching these equations with mine. Just
to make sure we are discussing the same problem....

The circuit is a voltage source
Vs(t) = 141.4 sin(wt-45)
driving a source resistor of 50 ohms and 45 degress of 50 ohm
transmission line that is shorted at the end.

My calculations suggest that
Vrs.total(t) = 100 sin(wt-90)
Irs.total(t) = 2 sin(wt-90)

which agrees with you column D but not the introduction which
says that the zero current is at 0 degrees. With -100 volts
across the source resistor at 0 degrees, the current should
be -2 amps through the source resistor at 0 degrees; in other
words, a current maximum.

Using superposition, I compute the the contribution of the
source to be
Vrs.source(t) = 70.7 sin(wt-45)
and the contribution from the reflected wave to be
Vrs.reflected(t) = -70.7 sin(wt+45)
which sum to
Vrs.total(t) = 100 sin(wt-90)
as expected.

So while I can construct an expression for Column D, the
contributing values do not agree with those you have
provided in Columns B and C.

Column E follows from Column D and my calculations agree.
And also with Column F.

> > > The spreadsheet addresses the following issues:
>
> > > Does the traveling wave carry power? Yes. The spreadsheet was built
> > > assuming that power is carried by traveling waves. Because the
> > > resulting wave form and powers seem correct, the underlaying assumption

> > It was not obvious which columns were used to draw this correlation.
>
> Column E and column F display power. Column F recognizes that if 100 watts is applied
continueously (on the average) over an entire 360 degree cycle, the final power applied
over time would be 360 * 100 = 36000 watt-degrees. Part of the power comes from the
reflection, part comes directly. Obviously, interference is very much at work in this
example.

Column E is the power dissipated in the resistor, and Column F
is the integral of Column and represents the total energy which
has flowed in to the resistor over the cycle. It is also the
average energy per cycle.

If you were to extend your analysis to compute the energy
in each degree of the reflected wave and add it to the energy
in each degree of Vrs.source(t) and sum these, you would

find that the instantaneous energy from Vrs.source and
Vrs.reflected does not agree with the instantaneous energy
dissipated in the source resistor. It is this disagreement
that is the root of my argument that the power in the
reflected wave is a dubious concept.

Using averages, the computed powers support the hypothesis,
but when examined with finer granularity, they do not.

thing is to consider how the reflected voltage sums with the forward voltage where it is
measured. Because the two waves are traveling in opposite directions, the measured voltage
is not the voltage applied to either Rs or the transmission line. This is why columns B and
C must be added to find the total voltage across Rs.

Whether one needs to add or subtract is more a matter of the
convention

being used for the signs of the values. When Vf and Vr are derived
using
Vtot = Vf + Vr; Itot = If + Ir
one would expect to have to add the negative of Vr to the contribution
from Vs to arrive at the total voltage across the source resistor.

Power into the transmission line is low when either the voltage or
the current is low; when either is zero, the power is zero.

Since the highest voltage occurs with zero current and the highest
current occurs with zero voltage, maximum power into the transmission
line occurs when the voltage and current are both medium; more
precisely, when they are both at .707 of their maximum values.

> This is just one example, but it seems like the power is accounted for here. We need another example where power can NOT be accounted for.

I suggest it is the same example, but the granularity of the
analysis needs to be increased.

3735. BNC Crimp Tool and crimp-connector

Newsgroup: rec.radio.amateur.antenna
Date: 2008-03-30 18:24:42 UTC
From: "J. Mc Laughlin" <jcm@power-net.net>
Message-ID: <9J-dnVL1K4x3R3LanZ2dnUVZ_gSdnZ2d@bright.net>
Source record: 26557

Dear Group:

It appears that I may be compelled to crimp BNC connectors far out in a field.

I searched the many thousand messages I have saved that were of value and found this from Mr. Brian Kelly from August 3, 2003:
If you're going to spend money, then be sure to buy plugs with a captive pin and pressure-sleeve ("top hat") cable clamp.

They are more expensive than the original MIL type, but much better for hand assembly and much easier to remove and re-use... in other words, they're good long-term value for amateurs.

An example is the Tyco/Greenpar 1-1478401-0. There should be a disassembled picture at www.farnell.com/uk - search for part number 3977754. (The parts aren't laid out in quite the right order, but you'll get the idea.)

Personally I wouldn't use crimp connectors without the correct tools to make the full six-sided crimps in the two different sizes required. Also they cannot be re-used, which makes them poorer value for (most) amateurs.

With the assumptions that the cable is RG58C/U type, that the connection will be well wrapped and the BNC connector is on the end of a very long piece of cable going to HF receiving antenna(s):

Questions: What have you found to be the most reliable BNC connectors of the crimp type?
What crimping tool is the most appropriate?

A crimping tool that may inexpensively be modified to crimp UHF (to RG213/U type cable) type connectors is desirable.

Thanks for your advice. No substitute exists for experience with a task that so easily can go wrong.

AMP makes connectors, and crimpers for coax- and they are quite
reliable- thats the good news. The BAD news is they are quite
expensive, and only crimp one size connector for each- one size for
rg58, one for rg-174 (?) The small stuff, used for baseband cables ,
and mux equipment, and another for UHF connecters . think these also
available for N types. You might look at their web page for info.

Also, IF interested, the CENTERS of a BNC connector is the same size
as the N connector, if you wish to make test cords- tho they obviously
DON'T lock to the female connectors- not good for a permanent
installation. --- Jim NN7K

Dear Jim: Oh my, are they expensive. For half the price, Steren
(sterenusa.com) makes a model 204-036 that deals with BNC, RCA, and F type
connectors. What looks like the same tool, is sold under Paladin name and
some house-brands. I wonder if anyone has used this tool?

Sometimes one must pay a high price to receive reliability and quality, but
that is not always the case. Someone put us onto a modest cost CAT5 tool
that we used at work for many, many connectors with almost no failures.

Thanks for you advice. I will put the AMP 58433-2 on the list to consider.

Mac, have a look at the dies and frame at:

http://rfshop.com.au/Products/Hardware/tabid/426/List/1/CategoryID/261/Cate
gory2ID/776/Level/2/Default.aspx

These are out of Asia and the tools work quite well. As you will see, there
are dies that include cavities for a range of cables and you may are likely
to find a tool that will suit many small cables on BNC / UHF / SMA etc.

The tools come into Australia branded HIT, you may find them listed with
retailers over there.

BTW, RFSHOP are great to deal with, and if look around there site, you will
see a range of inexpensive, but good quality connectors etc.

Owen

One look in a mirror should convince you otherwise.

> You *have* found it hard to the do the math;

Nope, I just think that instantaneous power math is a waste of my time. Seems to also be a waste of your time.

> Your explanation is not complete until you can identify
> the element that stores and returns the energy and its
> energy transfer function.

I simply don't have anything at all to say about instantaneous powers. In my opinion, such is a waste of my time. You might as well be demanding that I produce the math for how many angels can dance on the head of a pin.

> Energy can not be destroyed.

Yet, you are trying your best to destroy the energy in the reflected wave. Since you cannot destroy reflected energy at the average power level, you are trying to destroy it at the instantaneous level.

Average is the only accounting that I consider to
be important and the only accounting that I am going
to do. I have added a disclaimer about instantaneous
power to my Part 1 article. I personally don't think
that anyone else cares about instantaneous powers.

If you need an instantaneous power article written,
please feel free to write it yourself. I wish you luck
but I personally consider it to be a waste of time.

The manual on the MFJ 259b warns that strong local broadcast band rf can cause problems with accuracy of the unit. The warning mentions strong AM broadcast signals. A new tall tower near my house is emitting a strong FM broadcast signal. When I hooked up my G5RV to the frequency counter input on my 259b, it immediately locked on at 100.500 MHz. The signal is so strong that I can hear the station at multiple frequencies when I tune across the FM broadcast band on a small FM radio. Could this be interferring with my attempts at getting reliable R-X SWR readings on my G5RV with the 259b?

One way to find out. Measure the SWR through a low pass filter that is meant
to be used at a transmitter output. These things usually start to roll off
at about 40 MHz, and will have around 80 db loss at 100 Mhz.

Absolutely. Ironically, among the many uses for an "antenna analyzer", the one they're least suited for is analyzing actual antennas -- at least in a lot of urban settings. What I've done is constructed a number of "half wave filters" which effectively filter out TV and FM signals without affecting the measured impedance appreciably on the band they're designed for. You do need one for each band, however.

A "half wave filter" has a unity voltage, current, and impedance transformation, and a 180 degree delay, at the design frequency, like a half wave transmission line, but provides a lowpass filtering function. They're broad enough that you can use one over a whole band without too much impedance error. It consists of a shunt C - series L - shunt C - series L - shunt C, with the reactance of every element except the middle C equal to 50 ohms (to mimic a 50 ohm transmission line). The reactance of the middle C is half the value of the others -- you can conveniently use two capacitors in parallel, each having the same reactance as the end capacitors. I generally use mica or NPO ceramic capacitors, and inductors wound on type 6 or type 2 powdered iron cores, for HF. You should test the filter by measuring several known impedances with it in series with the impedances, and with it removed.

You can make a highpass version, too, by exchanging the Ls and Cs. In your case, though, you need lowpass ones.

Dear Owen: I am obliged for your suggestions and the RFShop reference.
Indeed, a set of dies for just the connectors of interest has some appeal,
and the HIT series has a good selection of dies. I have yet to locate where
the HIT series are available on this side of the Pacific, but I shall keep
looking.

I note again the comment made back in 2003 about the desirability of a hex
crimp. It turns out that Steren makes a single purpose tool (204-005) that
performs a hex crimp on BNCs and costs about the same as a HIT die. The
mating connector in quantity appears to be about half a dollar.

So many choices. Thank you again. 73, Mac N8TT

He's getting RFI at one frequency. I was thinking an open quarterwave coaxial stub tuned to 100.5 MHz would serve to trap the offending signal, and be easy to implement. Cut it a tad long from the calculated length, connect it to the analyzer input using a tee adapter, and "tune" it up in frequency using a pair of wire cutters:

246/100.5 = 2.45' (or 2' 5-3/8") * Vf

You state that your hypothesis is that for this specific
circuit, "the energy in the reflected wave is dissipated in
the source resistor". This claim is amenable to analysis
using instantaneous energy flows. When so analyzed, the
hypothesis fails.

I can see why you want to limit the kinds of analysis
applied to your hypothesis, but that is not how science
works.

If you wish to narrow your hypothesis to "the average energy
in the reflected wave is simply numerically equal to the
increase in the average dissipation in the source
resistor" I will not object since that hypothesis would
be completely accurate and not misleading.

As long as you wish to claim that there is actual energy
in the reflected wave, and that this energy is dissipated
in the source resistor, you must be prepared to offer a
full accounting.

Not at all. I've learned a new (at least to me) technique
for analyzing where the energy goes. I've increased my skills
with complex numbers in Excel. I have a firmer grasp about
power computations. I've explored the tautology of
Ptotal = Pforward - Preflected. I've learned a bit about
macros in Excel. I've tried Calc and found it wanting.
I've looked at energy flows in circulators. I've explored
active and passive circulators. And I've proved your
hypothesis to be false.

Not a waste at all.

> > Your explanation is not complete until you can identify

A higly convenient opinion since it allows you to continue
to believe your hypothesis.

> You might as well be demanding
> that I produce the math for how many angels can
> dance on the head of a pin.

No. Instantaneous flows *can* be computed. Angels on a pin
are a little more problematic.

> > Energy can not be destroyed.
>
> Yet, you are trying your best to destroy the energy
> in the reflected wave.

Since you start with an unshakeable belief in the
existance of energy in the reflected wave, this would be
your natural conclusion.

Those of us whose beliefs are not so fixed, evaluate
the proofs and come to the conclusion that energy in
the reflected wave is a dubious concept.

> Since you cannot destroy
> reflected energy at the average power level, you
> are trying to destroy it at the instantaneous
> level.

"Average" is just a data reduction from "instantaneous".
An agreement of averages is not a proof of anything
except that the "averages are numerically equal".

> power to my Part 1 article.

But the meaning of the disclaimer is not clear to the
reader. You really need to restate your hypothesis to
remove the possibility of misleading the reader.

I would suggest something along the lines of "My
hypothesis is that the average energy in the reflected
wave is *numerically* equal to the increase in dissipation
of the source resistor. It should be noted that this
says nothing about whether the energy in the reflected
wave is actually dissipated in the source resistor."
That would be completely accurate and very unlikely to
be misconstrued by the reader.

> I personally don't think
> that anyone else cares about instantaneous powers.

I am sure some do not. But anyone interested in a full
understanding does.

> If you need an instantaneous power article written,
> please feel free to write it yourself. I wish you luck
> but I personally consider it to be a waste of time.

It is convenient when you just ignore the analysis
that disproves your hypothesis. But it does not make
the hypothesis more correct.

First, let's correct your out-of-context quotation.
Here is what you should have quoted: "When zero
interference exists at the source resistor, the
energy in the reflected wave is dissipated in the
source resistor."

This is actually a fact for both average powers
and instantaneous powers. Since all of your examples
are associated with a non-zero level of interference,
they are irrelevant to the stated conditions.

Here is a quote from that article:
"Please note that any power referred to in this paper is an AVERAGE
POWER. Instantaneous power is irrelevant to the following discussion."
The word "average" is implied in every statement I make.

> This claim is amenable to analysis
> using instantaneous energy flows. When so analyzed, the
> hypothesis fails.

No, it doesn't fail. You have simply failed to satisfy
the zero interference precondition.

> If you wish to narrow your hypothesis to "the average energy
> in the reflected wave is simply numerically equal to the
> increase in the average dissipation in the source
> resistor" I will not object since that hypothesis would
> be completely accurate and not misleading.

That is, in fact, the only hypothesis presented in
my Part 1 article. Since my hypothesis never applied
to instantaneous power, I don't have to narrow the
hypothesis. My article stands as written. Please
cease and desist with the unfair innuendo.

> Not a waste at all.

Obviously, your opinion differs from mine. To the best
of my knowledge, you are the first person to spend any
mental effort on instantaneous power. If that's what
you want to do, be my guest. I consider it to be little
more than mental masturbation, "of limited utility" as

Hecht said.

In fact, I proved my assertion was true even at the
instantaneous power level when the "zero interference"
precondition is met.

> Since you start with an unshakeable belief in the
> existance of energy in the reflected wave, this would be
> your natural conclusion.

Since you are incapable of producing an EM wave devoid
of energy (or an angel dancing on the head of a pin) both
concepts are unrelated to reality IMO.

Your challenge is the same as it has always been. Just
produce an EM wave containing zero energy and get it
over with.

What is it about "Please note that any power referred to
in this paper is an AVERAGE POWER. Instantaneous power
is irrelevant to the following discussion." that you
do not understand?

> I would suggest ...

I would suggest that you write your own article.
Mine stands as written in the *stated context*
of zero interference and average powers. I am
not interested in attempting a unified theory
of everything.

>> I personally don't think
>> that anyone else cares about instantaneous powers.
>
> I am sure some do not. But anyone interested in a full
> understanding does.

Anyone interested in a *full* understanding would
take the discussion down to the quantum level which,
interestingly enough, you have chosen to ignore.

> It is convenient when you just ignore the analysis
> that disproves your hypothesis. But it does not make
> the hypothesis more correct.

If you think your unethical innuendo, out-of-context
quotes, and straw man arguments disprove anything,
I feel sorry for you.

Once again, the context of my Part 1 assertions is
ZERO INTERFERENCE and *AVERAGE POWERS*. You have
disproved nothing so far. You were even taken aback
when it was true at the instantaneous level in the
context of zero instantaneous interference.

Keith Dysart wrote:
> Perhaps, but it is highly improbable that it falls apart
> in a manner that ends up supporting the original failed
> hypothesis.

Since the original hypothesis is in the context of
zero interference (and average powers) it has not
failed. So far, I have made no assertions about
conditions when interference is present as it is
in all of your examples. None of your observations
are relevant to my Part 1 article because they are
all outside the stated context of the article.

The challenge for you is to present a zero interference
example for which my hypothesis is false. So far, you
have failed to do so.

I have asserted, "If zero interference exists, then 'A'
is true". You have said 'A' is not true when interference
exists. I actually agree with you but it is irrelevant
to the stated 'if' portion of my premise. Where did
you study logic?

Maybe you don't realize that if the 'if' portion of
an 'if/then' statement is false, the entire statement
is true, by definition.

My assertions about conditions when interference is
present will appear in Parts 2 and 3 (which would have
been completed by now if I had ignored your diversions).

Depends on the dielectric material. There are some 10kV 1000pF caps out there that have a fair amount of loss at RF and a fairly big temperature coefficient, so as they get hot, the tuning will change.

What you want to know is how much current is flowing through the capacitor. Then you can look up the capacitor ratings and figure out if it will explode, melt, or work just fine.

Think about what that trap is doing, too. At frequencies above the resonant frequency, any current will be flowing through the capacitor (because its reactance is smaller, while the inductor's reactance is larger), but, the current might actually be pretty small. Say you have a 10-20 meter antenna with a trap. On 10m, you want the trap to "turn off" the 20 meter extension, so it's roughly at the "end" of the 10m dipole. That's where the current is lowest.

At frequencies below the resonant frequency, the capacitor's reactance is higher, and more of the current flows through the inductor.

That's basically what's going on. It's actually the ferromagnetic domains doing the vibrating in the ceramic (i.e. there's no physical displacement), but it's the losses in that vibration that's responsible for the dissipation.

I don't know if your capacitors

Silver mica works fairly well at HF (assuming you stay within the ratings).. mica is a low loss dielectric

I tried a 2.5 MHz HPF with an MFJ analyzer to measure a 75 m antenna.
Unfortunately there is too much phase shift. Really not usable below about 5
MHz. The MFJ works fine during daytime hours before all the signals come up.

As I tried to understand your problem, I finally realized that it was really my problem. As a result, I redid the spreadsheet. I now label "my formula" as being erroneous, this because it does relate to the current, not the voltage, and must be displaced by 45 degrees.

My formula (labeled erroneous) was the result of the formulas of columns B and C added with trig identities. What I did not realize was that the adding, while correct, rotates the phase. The formula is wrong because it does not recognize the phase shift that had been assumed for line one.

> Column E and column F display power. Column F recognizes that if 100 watts is applied continueously (on the average) over an entire 360 degree cycle, the final power applied over time would be 360 * 100 = 36000 watt-degrees. Part of the power comes from the reflection, part comes directly. Obviously, interference is very much at work in this example.

I think the energy adds correctly now. Of course it depends upon how we measure the energy because energy is stored in the transmission line at all times, but the stored energy is only measured across either Rs or the transmission line. We do not measure the energy within the transmission line in this example, which is the sum of the applied power for 90 degrees.

> Using averages, the computed powers support the hypothesis,
> but when examined with finer granularity, they do not.

I think each degree has the correct power now. I apologize for the errors, and hope that I have them all removed.

Because the two waves are traveling in opposite directions, the measured voltage is not the voltage applied to either Rs or the transmission line. This is why columns B and C must be added to find the total voltage across Rs.

> ...Keith

I hope I have the spread sheet displaying correct values now. Thank you for your careful analysis.

I doubt that this will satisfy your power location concerns because the spread sheet shows more power being delivered to the resistor than is present in the voltage. This is because the impedance of the power equation has changed due to the contribution of the current component. Consider that for columns B and C, the same current flows whether the voltage in B is applied or the voltage in C is applied. This can only happen if the impedance seen by each respective voltage is different. This is interference at work

The main reason is that a recent change by my ISP apparently resulted in my not seeing a lot of postings. This morning it said there were about 5,000 unread messages, and I've been scanning through the more recent ones. I'll make it a point to find the thread you mention and respond.

It would be very helpful if you could tell me the date you started that thread.

My understanding is that this is not the biggest influence at HF -- there's so much atmospheric noise down there that even with a pretty poor receiver (noise figure-wise) the MDS is usually just about the same as with a much better receiver.

> In my line of work, which is Radar engineering, we use a standard
> temperature T = 270 Kelvin to model the noise originating by natural

Have you seen the graph in, e.g., Krauss's antenna or EM book? T=270 is a poor model at many frequencies. (Granted, if you're doing narrowband designs, it'll just be some offset error that's probably not too much worse than, say, +/-3dB.)

From watching this thread I get the impression that -- at least on HF again -- the (lack of) capture area is the much bigger problem than the mismatch is.

Please disregard my recent response.

There's still something strange about either my newsreader client or my ISP. The quoted message, as you see, indicates that it was posted by Roger Sparks, to whom I thought I was responding. But closer examination shows that it was actually posted by Cecil. Consequently, my answer is different. The reason I haven't responded is that I plonked Cecil quite some time ago so I wouldn't be dragged into his tiresome and unending alternate reality arguments. So unless someone quotes him (or the system malfunctions, as it has here), I don't see his postings at all. And if and when I do, I'm not inclined to respond. Other readers who disagree with my postings on this topic are welcome to question it, and are encouraged to look at the evidence given in all people's postings to decide for themselves what the facts are.

I apologize to Roger Sparks for the misattribution.

After posting previosly, I got to thinking that interference here is wrecking the analysis of Column D. The traveling wave analysis is correct (Column H). Only one current is flowing through Rs, and the current is not enough to supply the power suggested in column D. While it is logical to add the voltages from Column B and Column C, the two voltages are often in opposition so they are not "seen" by Rs. As a result, we must have a reflection from Rs that I am not taking into account.

The "half wave" filter I described makes no impedance disturbance only at the frequency at which all the components have the same reactance. The cutoff frequency, as I recall, is close to that frequency. So you'd have to make a filter with a cutoff close to 3.8 MHz, not 2.5 MHz, in order to measure a 75 m antenna if you're using this kind of filter. There are, of course, many other types of filters, but just about any will affect the impedance measurement except perhaps over a fairly narrow range of frequencies.

Since there is just one frequency that's causing trouble (apparently),
and since I gather that it's removed in frequency a pretty good
percentage from the frequencies of interest, it may be possible to
block it with a fairly sharp notch filter. As Roy notes, the 100.5MHz
FM signal may not be the only one causing trouble, but assuming it is,
try this: shunt across the input to the analyzer, place a series LC.
The L: 9 turns #12AWG bare copper, 0.75" ID, 1.5" long (about 750nH,
SRF about 150MHz). The C: a high quality 1-5pF trimmer capacitor.
I'd recommend a good piston trimmer, but they tend to be expensive
unless you happen to have some or can get some surplus. Depending on
the exact coil characteristics, the cap will adjust to a 100MHz
resonance at about 2pF. By keeping a high L:C ratio, the notch will
be sharp--not as deep as it could be with lower L:C, but it should be
deep enough if you use good construction practice. The suggested
values should give you at least 25dB attenuation at the notch
frequency, and should look practically like the capacitor value (about
2pF) at HF.

Cheers,
Tom

> > I doubt that this will satisfy your power location concerns because the spread sheet shows more power being delivered to the resistor than is present in the voltage. This is because the impedance of the power equation has changed due to the contribution of the current component. Consider that for columns B and C, the same current flows whether the voltage in B is applied or the voltage in C is applied. This can only happen if the impedance seen by each respective voltage is different. This is interference at work
> > --
> > 73, Roger, W7WKB
>
> After posting previosly, I got to thinking that interference here is wrecking the analysis of Column D. The traveling wave analysis is correct (Column H). Only one current is flowing through Rs, and the current is not enough to supply the power suggested in column D. While it is logical to add the voltages from Column B and Column C, the two voltages are often in opposition so they are not "seen" by Rs. As a result, we must have a reflection from Rs that I am not taking into account.

Column B is correct; this being the voltage produced by the source
divided by two.
It is also the forward voltage on the line.
Vrs.source(t) = Vf(t) = 70.7 sin(wt)

Column C is the reflected voltage (not the reflected voltage impressed
across the
source resistor). The reflection coefficient is -1, and the delay is
90 degrees
so the reflected voltage at the generator is

Vr(t) = -1 * Vf(t - 90 degrees)
= - 70.7 sin(wt-90)
= 70.7 sin(wt+90)

But Vr is impressed across the resistor in the opposite direction to
that of
Vrs.source, so the equation for total Vrs is
Vrs.total(t) = Vrs.source(t) - Vr(t)
thus column D should be B31-C31.

Alternatively,
Vrs.reflect(t) = -Vr(t)
and then
Vrs.total(t) = Vrs.source(t) + Vrs.reflect(t)

Column E is correctly computing the instantaneous power from Column D
since
P(t) = V(t) * I(t)
= V(t) * V(t) / R
= V(t) * V(t) / 50 (in this example)
but has the wrong data because of the error in Column D.

Column F is integrating the power to yield either the energy in a
cycle or
the average power per cycle (though presented in unusual units).

I agree G is erroneous and I am not sure what H is computing.

I find this topic very interesting, including the mandrill part :)

We all want to have small, broadband, eficient antennas. I believe Art is right in his original post, today we can have all these characteristics in the same package. There is no law of physics forbidding that. Through advances in computation power we can achieve today in months what took decades in the past and there is much research directed at these kinds of new antennas. Eventually everyone will be able to choose and model his own antenna based on the characteristics one wants, but without the cumbersome dimensions, without significant bandwith limitations, without major efficiency compromises. I believe the tradeoff (for it has to exist one) will be ease of manufacturing.

Incidentally these new antennas have a lot to do with what Art defines as equilibrium although I don't think he has a clear enough definition. But it's all related to patterns, patterns which can be found everywhere in nature an which can be expressed almost entirely through matemathical formulas. Scaling of antennas is clearly possible, despite of what the Chu-Harrington limit states (or to be fair, by applying them in a new way).
I eagerly await the day when the 80 meter dipole will be replace by a small device the size of a shoe box (although it might be a bit larger in the beginning :)).

Regards,
Robert

Unless (as in the OP) the source of the interfering signal is a
line-of-sight VHF/UHF broadcast station -- the nearby fields of which can be
very high, and little affected by the time of day.

Hi Richard,

I have a pair of computer speakers sitting on my desk that completely out
perform the so called ultimate hi-fi floor mounted tower system speakers I

bought 35 years ago for the equivalent of several thousand dollars in today's money. The old speakers still work just fine but the audio experts have learned how to squeeze that performance out of a speaker that old audio theory predicted couldn't possibly work. Just how does a 3 inch speaker in a cabinet the size of a couple of books manage to produce notes from 20 Hz - 20 kHz? To be fair, the small speakers can't fill a room with sound in the same smooth way that a larger speaker cabinet can, but for everyday use in a small modern house or apartment they are more than adequate for the majority of people.

It seems to me that Art and others are pursuing a similar path at RF. The aim being to produce an antenna that punches out a signal from a physically small area. It may not perform quite as well as a full size half or full wavelength antenna, but it will work well enough for most people with small gardens or limited real estate for an antenna farm.

Clearly there are considerable differences in dealing with sound waves and RF but I believe that a principle has been established that it is possible to 'simulate' the performance of a larger system using physically small components. Art may not be the first to get there, but he seems to be having a damn good try and someone, somewhere will eventually succeed.

Mike,
I am already there. Regardless of the confidence I have in my own
findings
I have cinsented for a stanger in another state to test it in a way he
feels comfortable with.
I might also remind you that the antennas are Small full wave antennas
which vastly different
to electrically small antennas that is often written about by many
including Chu!
As far as equilibrium goes it is adviseable to go back a few hundred
years when
scientists observed a static bubble and wove a mathematical response
to their puzzle.
Most people on this thread do not have a thorough understanding of the
masters laws
which are derived around the term equilibrium. Many were agast at the
idea of adding a time variable
to Gaussian law since the correllation between a closed boundary and
equilibrium
was to complicated for them to understand. Then there were those who

disliked the idea of static particles
being electrons and wanted me to state it was a part of an electron
that passed in a straight line thru the atmosphere.
These people will go into a state of shock if I called partices by the
name of neutrinos no less.
All because of the stance they have taken that all is known about
radiation. It was the small step
that I took that scientists have been looking for for years when they
began
to lose faith in classical physics snd the laws of Newton and turned
to address numourous new sciences
for answers.Now they may retreat and bind themselves more firmly to
the classical science and the pursuit of a universal law
which Einstein seached so hard for.
As far as 'all is known' older people hate change with a vengence and
will fight to the death against it with
the short time they have left on this earth . Fortunately the younger
generation always comes along with an
inquisitiveness that cannot be suppressed and are willing to rebuild
where past structures disappear below the sands.
Small FULL WAVE radiators are here now where a single element can
supply the same gain as a planar array.
Single elements that can be made with two degrees of freedom that can
also be stacked to add an extra
degree of freedom for the smallest WiFi device. I now await the
standard comments that comes along after each of my patents,
I new that already! It is really not all that special! It was me who
gave you the idea in the first place.
Anybody can get a patent ! That was already known and invented before.
It is not my fault that people didn't make it earlier!
What use is it?> We already have good antennas!
Yup. Small full wave antennas are now here that can cover all
frequencies, not just all bands!
Moxon was just a tad to late to see the new antennas for small gardens
in the U.K.
Best regards
Art Unwin KB9MZ....xg (uk)

Richard,
Surely you are aware of the two vectors which represent the electrical
field and the magnetic field
If the current carrying member is a diamagnetic material both of thes
vectors will be in the same direction.
But the diamagnetic material is just a myth of mine right ? So I will
go along with you and say the vectors are at right angles to each
other
just like all your books say. But later in your books they then refer
to the vector "curl. This vector must be added to the two vectors at
right angles to each other so a resultant vector can be found. Now you
and the books state that radiation is at right angle to the axis of
current flow.
So the question becomes'Where must the 'curl' vector be placed in
general terms to justify the right angle radiation statment that all
your books
apparently parrot? Simple question isn't it? Did all your learning get
discarded because of books because you are unwilling to challenge
them?
Terman was not made a saint, nor was Kraus or Feldman or even
Einstein. None of these would state that they never have made a

mistake.
Stop imitating Andy Capp and draw on your own thoughts for once
Art

It's not a "reflection" of a single wave, Roger, it is
a "redistribution" of energy caused by superposition
of two waves accompanied by interference. Eugene Hecht
explains it all in Chapter 9: Interference in "Optics".

For anyone who thinks he is already omniscient
about EM waves, I would highly recommend reading
Hecht's chapter on interference.

I had to chuckle when I read this Cecil. First I looked up the word "omniscient" to refresh my memory about meaning, but then I thought "anyone who thinks he is omniscient is not about to read the works of others and learn new tricks". Just human nature.

You can see from my postings that I am still trying to better understand the wave and reflections, still looking how to describe the energy distribution within the cycle. The storage of the redistributed energy must be close to the wires of the circuit so we should be able to describe it mathmatically, if I just knew how. We are probably close on the spreadsheet, but it is not yet crystal clear in my mind.

Many thanks to all for the recommendations. I got reasonable results today by measuring antenna impedance and SWR through my MFJ 993b tuner with the tuner in "bypass" mode. Apparently the tuner, even in bypass mode, is affording some isolation from the offending FM rf. At 14.2 MHz EZNEC predicted an input impedance on my 50 ohm line of 38.78 - j49.01 at an SWR of 2.97. My actual measurement with the 259b looking into the bypassed 993b tuner was 17 -j28 at an SWR of 2.9. Similar "ballpark" agreement was attained on 40 and 80 meters. I'm certain building a filter of some sort, as you all have suggested, will yield better results. Wish I had a way to measure the strength of that FM signal. My oscope is only good to 50MHz.

Uhhh. actually there ARE laws of physics putting some pretty severe constraints on it, if not actually forbidding it, if you also accept the constraint that the material of which you make the antenna has finite resistance.

Through advances in computation power we can achieve

> fair, by applying them in a new way).

Chu and, later, Harrington said nothing about bandwidth, by the way. They were more concerned with directivity and size and stored energy (the latter of which ties to efficiency and bandwidth).

Also, even if you created a very small antenna with high efficiency (e.g. with superconductors), the fields around such an antenna will be quite intense, so while the antenna may be small, its near field will be pretty much the same size as the dipole it replaces, so you'll need to put that tiny antenna way up in the air with a non-conductive, non-lossy support to get it away from everything else. Finding a feedline might be a bit of a challenge. One has to be careful when one draws "the boundary" of the antenna.

In practical terms, the size of an antenna isn't just the dimensions of the metal, but the "keepout" area within which you can't tolerate any intrusions and still keep the same antenna performance (i.e. a 40m dipole laying on the ground doesn't work nearly as well as a dipole suspended 10 feet off the ground)

For that matter, avoiding the breakdown of air might be a problem. Consider a tesla coil, which is basically a fairly inefficient (in terms of radiated power for RF input power) small antenna for 100 kHz or so. The limit on performance for the tesla coil isn't thermal heating of the coil, but HV breakdown. Even a few hundred watts into a "shoebox" sized coil will have breakdown problems (and this is fully predicted by Chu's analysis... it's that "energy stored in the field" problem)

Hi Mike,

I have a set of 30 year old Pioneers that still kick ass. The Pioneer
amp feeding any other set drives them into distortion where the
Pioneer speakers still have more range to go.

Never needed to push the amp above 4 to be heard outside.

OK, so much for the merits of qualitative reports, otherwise known as
testimonials. Proves nothing.

>The old speakers still work just fine but the audio experts

Magnetics got better, and theory stayed the same. Performance
followed the theory's prediction of new magnetics is all. This isn't
a mystery is it?

Care to name your speakers' model and manufacturer, or did you form
the cone and wind the voice coils around a selected magnet by hand?

> people with small gardens or limited real estate for an antenna farm.

Nope.. there's a significant difference between the speakers and the antenna, and that's the fact that the amateur user of the antenna is power limited (by regulation). In the speaker case, they trade off efficiency (acoustic watts out for electrical watts out) because electrical watts are cheap these days (not so back in McIntosh tube amp days...) You can tolerate a 1% efficient design that puts out 100mW of acoustic power with 10W electrical power in. (note that 120dB SPL = 1 Watt.. a symphony orchestra, at full tilt, is about a watt of acoustic power, and I daresay you couldn't tolerate a whole orchestra in your office)

OTOH, a 1% efficient antenna design is pretty crummy. A dipole is probably on the order of 70% efficient (RF power radiated into the far field vs RF power at the feedline). A mobile antenna (which everyone will agree is not particularly efficient, even if you argue about the actual magnitude) might be 5-10% efficient (10dB down).

As a practical matter, you can get away with a 1% efficient antenna, particularly if you're not looking for "link reliability"... The propagation loss between you and some arbitrary point could easily vary by 100 dB, so you just wait until propagation is "good enough" to work the guy with the 0.1W you radiate. Of such are "worked 300 countries on two bedsprings" sorts of stories made. Folks work around the world on less than a watt radiated, just not "on demand".. they keep trying until

conditions are just right and they "get lucky".

So, on that basis, you could probably fire up your 1500W amplifier into
a compact loop antenna that's a meter in diameter, and work the world,
eventually.

I made the change in Column D and the trend is more believable in Column E. I think the math here is noncommutative in the sense that time must rotate forward. I think this change does that even though the average power results stay the same.

Here's an even better idea.

Dump Hecht and read about interference in Born and Wolf. Chapter VII (in the 7th edition) is one of the main contributions. I particularly like Section 7.6. In this section the authors derive a general set of equations that deal with all sorts of reflection configurations. There is no need to worry about constructive or destructive interference. The equations smoothly transition from one to the other as appropriate. The equations don't fall apart as the reflection goes to zero. No "redistribution" is needed.

This is the way physics typically works; it is not necessary to separate superposition from interference or separate constructive from destructive. If the analysis and the equations are correct they will work for a wide range of parameters. Equations that must be fine-tuned for every possible change in reflection coefficient or other parameters are very limited and most troublesome.

Jim,
With all due respect a discussion is futile if you stray from the
concept of
a small FULL WAVE antenna and use the ELECTRICALLY SMALL antenna
as a straw man. The electrically small antenna is a fractional wave
antenna
which is represented by a series circuit. This is totally different
to a parallel
tank circuit. This correlates to a pendulum being cast as a weight
that comes
to a abrupt stop and instead of swinging up goes back from the bottom
to the
top from whence it came! A electrical small antenna assumes an
awefull lot
as to the mechanics of action involved in a full period. The tank
circuit is a
good example that shows that all segments of a period in terms of area
are exactly the same
where the tank circuit clearly shows that radiation occurres only in
the last
quarter of a period! The idea or concept of a fractional wave antenna
came
from the assumption that a sino soidal pattern can be seen as four

areas
under a line which can be considered the same as four times a quarter
segment,
a concept around which the NEC programs were formed. You NEVER get
radiation
at every quarter segment of a period. The concept implicit in Maxwells
laws is
that equilibrium is a given which means that the root C L portion is
that of a
full wave antenna as a minimum.
All the laws of the masters are based on a stable boundary at the
beginning and
at the time for a period of time., Time has removed a lot of memory of
the human race.
I suspect that the NEC programs around the current flow OUTSIDE the
arbitary boundary
that allowed them the successes they have gained without having to
consider
the mechanics of the innards within the boundary.

I believe ease of production is a subjective term. To obtain energy
one must consume energy, there's no free lunch. But ease may be
considered 'convenience' to us, i.e. what suits our production
capability better.

>
> 40 years ago they said DNA and genetics would allow us to design our

Genetics have indeed contributed to most important advances in our
understanding of the human body. Instead of relying only on physiology
and anatomy, we can now have a glimpse at the 'programming language'
at the core. What use do we put it to, that's a different problem.

That's a bit of devil's advocate stance, isn't it? :) You can't
seriously say that modelling software didn't bring something to the
table.

That's true, I am not an expert in this field, I only try to stay up
to date with the technology, feel free to correct me if I'm wrong, but
I have seen many advancements in this direction lately.

Since my example is *your* example (q.v. your Fig 1-1), your
example has non-zero interference (as you state above), so
you have just said that your example violates the stated
conditions.

Or are you going to say that the circuit exhibits interference
when an instantaneous analysis is performed, but knows that
it should refrain from doing so when only an average analysis
is done?

> Here is a quote from that article:
> "Please note that any power referred to in this paper is an AVERAGE

> The word "average" is implied in every statement I make.

Yes, "implied" is the word. Why not clearly state that, while the
average energy appears to be dissipated in the source resistor, the
actual energy is not.

Or *is* the intent to deceive?

> > This claim is amenable to analysis
> > using instantaneous energy flows. When so analyzed, the

If the precondition fails for the circuit, then it fails for
the circuit.

You insist that the narrowing is "implied", but then
refuse to explicitly state such to make it clear to
the reader. Why?

Yes. It does not support your hypothesis, so it is wise
to ignore it.

> In fact, I proved my assertion was true even at the
> instantaneous power level when the "zero interference"
> precondition is met.

Ah, yes. X**2 + Y**2 = (X+Y)**2 only when X or Y equals 0,
which for the example at hand applies at exactly 4 instances
per cycle.

The rest of the time the circuit exhibits interference.

> over with.

Tis a problem isn't it. You won't let go of energy in the reflected wave long enough to even explore the circuit to discover the inconsistencies that result from the belief.

You can not find a reason why instantaneous analysis should not work, but the conclusions are uncomfortable, so you decide that Hecht has told you not to bother, and you stop. Without knowing why.

After many posts and back and forth, I understand. But the
poor first reader will miss the implications: that the
imputed energy in the reflected wave is not dissipated
in the source resistor.

Why not save the reader the challenge and just state it
clearly?

> > I would suggest ...
>

> take the discussion down to the quantum level which,
> interestingly enough, you have chosen to ignore.

Yes. I have stopped at the level that disproves that the
imputed energy in the reflected wave is dissipated in
the source resistor. That is sufficient for me.

I do not think that deeper analysis will show this to
be wrong, but you are invited to do so.

On the other hand, average analysis can be shown to
produce misleading results by applying instantaneous
analysis. You should be interested because it disproves
that the imputed energy in the reflected wave is
dissipated in the source resistor.

I was? If so, I have now moved beyond. Especially since
you now assert that the circuit does exhibit interference,
the hypothesis becomes moot.

Good that you agree. And now that you state that the
circuit exhibits interference, it might be best to
withdraw your example.

Believe it or not Jim but I presently have a 160 meter antenna (full
wave)
wound on a metre loop that is resonant and can be used to work the
world.
It is hanging in the yard right now and obviously is very efficient at
what it does.
Covers the whole band to. Paid a dollar at the dollar store for the
hoola hoop!
Don't need to add capacitors and inductances evry few KHZ !

Ok, it was my mistake to not clarify 'high efficiency'. By that I
meant 'at the same order of efficiency as normal scale designs'.
I am currenty interested by what I have seen claimed as 'compacted
antennas', which behave similar to normal ones, except their
dimensions are smaller, X-axis wise at least. That those designs do
not perform as well or better than their counterparts is no problem
to me, as long as the figures are in the same ballpark. That would
mean they still are more efficient than previous designs which
attempted to solve the problem of physical dimensions, which is an
advancement in my book. That some other unexpected features as the

broadband factor may appear is only a bonus, because we can achieve
that with full scale antennas too.
To be more specific, I was reffering to such designs that reduce the
scale of antennas in at least one axis:
http://adsabs.harvard.edu/abs/2004ITAP...52.1945P
http://ctd.grc.nasa.gov/organization/branches/amosb/RCA_RESEARCH/RESEARCH_mini-antennas.ht
m
http://ntrs.nasa.gov/details.jsp?R=362773
http://ntrs.nasa.gov/details.jsp?R=470415
I have seen some of them described as fractal trees, but the
information is relatively scarce. I know research is continuing on
this subject and even found some info at a website somewhere but I
can't remember where. Since you probably know more about them than me,
I would appreciate some guidance here too :)

You mean it's very efficient at hanging in the yard? :)
Joking aside, I'd be interested in a *NEC file. Is it possible to
model, or is it restricted by the number of segments?

Robert

Robert, the Fractal can now be considered obsolete when compared to
mine.
The person who is testing my antenna is a member of this group.
Maybe he will drop a bone regarding this new antenna of mine so I can
have some credability. For years I have been insulted on my findings
and frankly I am getting fed up.People stated that I did not have such
an antenna,
A $5000 stake was put up by an Aussie (they bet on anything) to say
that he believed me.
Not one of the talking heads were willing to take on the Aussie and
win big.
As I stated they are mostly talking heads and nothing else.

Restricted by the number of segments but I have tested enough of the
diifferent designs
to know what I am talking aboutand only a few can be programed but
with limited segments
it can only provide guidance. MAYBE one day I will supply the patent
request number
I received last year as well as the following patent number but the
number of insults
have ruled that possibility out. The person who is testing it never
insulted me and
wanted badly to be on the inside of this new antenna. Sooner or later
the PTO will provide all.
The hula hoop was just a design for checking, The one I have now is on
a tip and turn set up
for the top of my tower for use with a mesh dish for 160 and all other
frequencies. I want to change the polarity
in situ !.
You never can stop learning once you get off the normal path and
penetrate the underbrush.
Suddenly the brush is behind and a clear valley bathed in sun light
appears and you have little time
to fully explore
There are many different versions of this antenna primarily to get a
complete range of impedences
for use as well as determining tilt angle e.t.c.

If the average interference is zero, the average
reflected power is dissipated in the source resistor.
All of your unethical lies, innuendo, and hand-waving
will not change that fact of physics.

The math is pretty easy, Roger. Keith seems to believe
that an inductor stores power which is, of course, a
ridiculous concept. As soon as I can see a character
that is smaller than 2 inches tall, I will respond.

You have yet to provide an example of zero interference
where the reflected power is not dissipated in the source
resistor. Until you do that, you are just waving your hands.

Examples containing interference will be covered in Parts
2 & 3 but the poor first reader will not get to read them
until you cease your present unethical behavior.

More precisely, the average value of the imputed reflected
power is numerically equal to the increase in the average
power dissipated in the source resistor.

It is not obvious why you reject this more precise, less
misleading description. Is there an intent to mislead the
reader?

You must have misunderstood. The power measured at the
terminals of an inductor is the rate of change with respect
to time of the energy stored within the inductor.

In calculus terms, the power is the derivative of the energy
within the inductor.

This is equivalent to the rate of flow of energy into
the inductor (or out of, if you choose a different convention
for the sign of the value).

You misunderstand. I am not attempting to do that. Though somewhat bizzarre, I have, for the purposes of this discussion, accepted your definition of interference.

And using your definition, that there is no interference when (V1**2 + V2**2) = (V1+V2)**2, it can be seen that for the circuit at hand, your Fig 1-1, there is zero interference in the terms you wish to add, four times in each cycle. From this one might conclude that the imputed reflected power is dissipated in the source resistor at four instances during the cycle. For the remainder of the cycle, again using your definition of interference, there is interference and hence the imputed reflected power is not all dissipated in the source resistor.

Thus any unqualified assertion that the imputed reflected power is dissipated in the source resistor is somewhat disingenuous.

> Examples containing interference will be covered in Parts
> 2 & 3 but the poor first reader will not get to read them
> until you cease your present unethical behavior.

But you have been claiming that the circuit of Part 1 already exhibits interference.

3805. 2 opposite parabolic reflectors in a single directional WIFI antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-01 10:34:36 UTC
From: JM <stasioNOQUIEROSPAM@NOQUIEROSPAMteleline.es>
Message-ID: <fst34h$e3i$1@aioe.org>
Source record: 26527

Hello. Is it possible to put two opposite parabolic reflectors in a single directional antenna of an WiFi Access Point (A.P.-A)?
In fact, the Access Point (A.P.-A) has two antennas, but it needs to send its signal very far, so it is not appropriate to put a directional parabolic reflector of aluminum foil on each individual antenna oriented each in the opposite direction.
Curiously, the signal from A.P.-A comes very well to another Access Point (A.P.-B) that is very far (and that has a directional parabolic reflector of aluminum foil), but the signal ot this A.P.-A comes very badly to the laptops that are near (near to this A.P.-A).
Is it possible to put two parabolic reflectors of aluminum foil in the opposite direction in each antenna of the Access Point (AP-A)? I am referring to a parabolic reflector of aluminum foil oriented to P.A.-B and another parabolic reflector oriented to laptops, this (2 reflectors) in each 2 antennaS. Will operate? Is there another better and equally simple solution?
Sincerely, JM

More precisely, at the *exact* time of arrival of the
reflected wave, the average power dissipated in the
source resistor increases by *exactly* the magnitude
of the average reflected power. Do you think that is
just a coincidence?

> It is not obvious why you reject this more precise, less
> misleading description.

Why do you use such unfair ill-willed debating techniques
based on innuendo and not on facts in evidence?

IMO, our two statements above say the same thing
with mine being the more precise and detailed.
I don't reject yours - I just prefer mine.

If the source of the increased dissipation in the
source resistor is not the reflected energy, exactly
where did that "extra" energy come from at the exact
time of arrival of the reflected wave?

Hint: Since the only other source of energy in the
entire system is the reflected wave, any additional
source would violate the conservation of energy
principle.

> in each cycle.

Correction for omitted word above: And using my
definition, that there is no *average* interference
when (V1**2 + V2**2) = (V1+V2)**2,"
Those are average (RMS) values of voltage.

The test for zero *instantaneous* interference is:
[V1(t)^2 + V2(t)^2] NOT= [V1(t)^2+V2(t)^2]
Those are instantaneous values of voltage.

Please correct your confusion about what I have said.
It is also clear that you don't understand when
interference exists and when it doesn't.

The instantaneous destructive interference equals
the instantaneous constructive interference 90
degrees later. That's why the interference averages
out to zero.

I believe, although I have not taken the time to
prove it, that the instantaneous interference is
zero only at the zero-crossings of the source
voltage and reflected voltage.

Again, the existence and magnitude of the
instantaneous interference is irrelevant to
the assertions in my Part 1 article. It is
obvious that the interference averages out
to zero over each cycle for the example
presented.

Source record: 26533

Hello,

Would appreciate your opinions on the following, please:

I have two scanners that I now have connected to a single Scantenna antenna
in the attic.
Receiving only.

The coax comes from the antenna to an A/B push-button switch I bought from
Grove.
It's a cheap switch, only $20, and made in China. They imply on their web
site that the body
is die cast metal, but it came to me with a plastic body.
http://www.grove-ent.com/SWC01.html

It's their SWC01, supposedly good to 2 GHz, and uses F connectors.

It appears identical to the TVC brand AB-90 switch from Home Network Supply,
which says on their description that
there is 90 db isolation.
https://www.homenetworksupply.com/products_details.aspx?theme_id=1454900095&department_id=
5736102740&sub_id=&product_id=5854125807

Pushbutton A is arranged so that it switches the antenna to the upstairs
scanner, while pushbutton B switches it to the coax leading to the
downstairs scanner.

Well, big surprise.

I can push button B, but yet hear (at much reduced volume) conversations on
the upstairs scanner.

Sure doesn't seem like 90 db isolation.

Is this what is to be expected on these cheap switches, or possibly just a
bum one, or... ?

Any thoughts would be most appreciated.

Thanks,
Bob

When the air breaks down around an antenna it is because the antenna
is not in a state of equilibrium. When a dipole is replaced by a quad
ala
a series circuit is replaced by a tank circuit it clearly shows that
the latter
is more efficient.This was firmly proven in Quito.Maximum radiation
efficiency requires equilibrium. Period

Bob;

90db of isolation is not the same as absolute isolation. There is still
some RF bleed from one line to the other line that a sensitive rf amp
can detect and send on to the detector.
Is there a reason for the a/b switch or just your feeling that you need
to switch the antenna from one radio to another.

Hi Dave,

The reason for the A/B switch is that I have only one Scantenna in the
attic, but I splurged over the years, and recently, and now find myself with
a Uniden and a GRE scanner.

Have one upstairs, and one downstairs.
So, want to switch my single Scantenna, depending on which I'm listening to.

Can always use a rubber duckie, I guess, on the GRE as it's a handheld, but
the Scantenna is much better, and I find that I'm using the GRE pretty much
as a base unit a lot.

Best regards,
Bob

Had a bit of luck when assembling the antenna to the pan and tilt
mechanism
prior to placing them on the tower. The PM motors do not have brakes
on them!
Fortunately the leverage of the tilting does not overcome the motors
inertia and I am in the clear.
For the future any ideas on a braking means to ensure stabilility in
position?
Both motors use chain drives and I suppose I could use solenoids to
tighten the chain
Regards
Art.

Try disconnecting the coax to the switched-out scanner from the switch and see if you still hear the stations. It is possibly just pick up direct into the cable etc.

Jeff

I don't think that my MFJ-259Z is charging properly. Its new and it has been on charge for over 6 hours and all the batteries are still reading 0 Volts. I'm using the PSU that came with it. It works fine from the PSU but doesn't seem to be charging. The switch inside for charging is turned on.. Can some one please advise me how to check it?

Thanks

Let me clarify my answer.
The natural resonance resistance can exceed 1000 ohms
thought with the same design the resistance can be lowered
at the expense of bandwidth. These design forms can be easily
modelled with or without a dish reflector. I introduced twisted
wire into the design to overcome the reduced bandwidth of
the other design to bring the resistance down to the 50 to
100 ohm mark for easy match to existing components.
Since the impedance resistance is drastically lowered when
using the standard design on the computor I am inclined only
to use the computor as a guide in that instance. The dish
modelled consist of parallel elements which obviously would
be a bear to tilt so many inaccuracies are built in except in
the case of the assembly being tilted which I am presently
researching.

3819. A Bit More On My Reception "Problems"

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-01 17:40:23 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <v96dnaYyRPEe7m_anZ2dnUVZ_sWdnZ2d@comcast.com>
Source record: 26540

Hi,

Just thought I'd ask, and mention a Bit More, Re My scanner AM "Reception "Problems"

a. is there a concept as "intrinsic antenna noise" for a receiving scanner antenna type ?

On AM scanner frequencies, around 118 MHz or so, I find my Disconne is a lot quieter than a Scantenna I have.

Both are in the same attic spot, and use similar coax downfeeds.

The Scantenna uses a balun of sorts; I think it's 300 to 50 ohm.

b. I've mentioned the problems I have in picking up, well, an airport control tower about 8 miles away.
I think I've come to the conclusion that it's "simply" a case of AM (always) being a lot noisier than FM.
Does this make any sense ?

If it's some sort of overload on the scanner, using the scanner ATTN does not help.

c. Funny thing is that when I use my JRC NRD 545, with either the Scantenna or the Disconne, it comes in really clear.
This is without resorting to any of the fancy filtering or notching that the 545 has.
Hard to understand why it should be so much better with just its basic settings.

Perhaps the fact that it uses DSP helps a lot on AM, in some manner ?

Bob

I ve used both the Paladin and AMP crimp tools. The AMPS work very well all
the time.
I have found some of the Paladins that dont work as well a others. This
usually means the shield is not fastened to the body of the connector as
well as it should.. Not knowing each tools individual history this may be
as a result of normal use and abuse as the poorer ones seem to have been
around for a while. I know the ones most recently purchased perform very
well.

The AMP tools is at least 20 years old or older and still works flawlessly.
However its never been on a tower or tossed around in a tool bag, thrown in
the back of a truck, or used for a hammer.

If you have ever tried to replace a number of N connectors while on a tower
even the price of the AMP tool becomes very economical.

One thing the Paladin tool has going for it is durabilty. I have dropped it
off of a 60 ft tower without doing any damage. Im not sure if the AMP tool
would handle this.

You my friend are a good example of what a redneck thinks.
In the past you have bragged about your lack of schooling
spouting about the times you didn't go to school. Now you have a
license
to operate a radio where you can excercise your freedom of speech at
will.
Unfortunately, as soon as you start vibrating you vocal cords you
instantly
reveal who and what you are. This is of immense inportance to the
rest of us
when considering whether to use our precious time to your utterings.
Go ahead and be a talking head but you will find that your audio lacks
propagation
in the subject of antennas
Have a happy day and be nice to those around you. You will never know
when
that last day of yours comes around despite your youthful age.

Dear Jimmie: Thank you for sharing your experience. That is just the sort
of thing needed.

After looking at information available on the WEB, it seems most likely that
Steren is the actual manufacturer. Steren makes both a BNC-RCA-F crimp tool
(204-036) (about $42) and a dedicated BNC crimp tool (204-005) (about $16).
I hope that someone who has used these tools will report their experience.

Thanks again, Mac N8TT

Prior Art... I have never "bragged" about not going to school.
I was expelled from school. Which means I really didn't have a
whole lot of choice in the matter past that stage.
But in the general scheme of things this means little, as most
schools don't teach antenna theory unless it's a specific college
course.
You have never heard my vocal cords vibrate, as you have never
talked to me. I doubt if you have even heard me on the air.

Being you are so highly educated, why is your spelling
so bad?
Seems to me you went to school, but either slept through
it, or had other things to think about.
In any case, you are the last horses ass that should be
braying about my education.
I educate myself, and have plenty of books laying around.
It's funny, I am self educated and oft speak about antennas,
but few people have any problems with what I write about.
If they do, it's usually some fairly minor detail.
You on the other hand, claim to be well educated, but
almost everything you spout is challenged as bafflegab,
pure untruth, or just plain horse crap.
What is wrong with this picture?
Prior Art, you make me feel gifted, being I seem to be
ahead of you as far as antenna theory, and I didn't
take *any* scholarly courses for it.
I think you should learn to write and spell a little better
if you are going to whine about other peoples lack of
education. Your "Queens English" is a mess.
What is your excuse for this problem?
I absolutely hated English when in school, yet I seem
to be doing a bit better writing it than you, even with my
sub par education. At least I have an excuse though.
Again, you make me feel downright gifted to be on par
with such a highly educated man such as yourself. :/
MK

I just did a search of the MFJ web page and it said
"No Items Found!" for an MFJ-259Z.

My MFJ-259B has a jumper for standard vs rechargeable
batteries. Perhaps your jumper in in the standard
battery position rather than in the rechargeable
position?

Actually, it is a "charger on" or "charger off"
jumper.

Hi Robert,

It takes only one to convince us, not many. Choose your best example
and then we can correct your impression of it being representative of
a new advance in technology.

Or we can simply skip the example and say there have been no new
advances, only new designs (not the same thing). Those new designs do
not strain the limits of 100 year old theory. They are only new
because of scale. We are no longer confined to the 2000M band for
QSOs (and most of those new designs are set in the cM bands).

G'day Group,

I have a new QTH with a steel roof (colorbond) and am thinking of putting up an unobtrusive (10m) vertical. I was considering mounting a quarter wave length of aluminum tube from the ridge cap, and use the roof as a ground plane. The roof slopes off either side at a shallow angle.

Anybody done this? Anybody see any problems?

thanks, Peter.

Peter, I have done this mounting the antenna on the peak of my workshop.
The result was an antenna with a near perfect match for 50 ohms as if that
matters that much.
Im waiting for warmer/dryer weather so I can replace it with a 5/8ths still
using the roof as a groundplane
and see how well that works.

Jimmie

Hi Robert,

Well, your list of URLs just let the air out of the tires on this ride
into the new century.

"Relatively scarce" information comes from one of several problems:
1. you didn't look hard enough and it is out there;
2. you didn't look hard enough and it isn't out there;
3. you don't have to look at all because nothing new is out there.

That aside, and given you poor usage of efficiency:
>Ok, it was my mistake to not clarify 'high efficiency'. By that I
>meant 'at the same order of efficiency as normal scale designs'.
"Same order?"

A garden variety dipole in the back yard can be 95% efficient. Now,
what is comparable within the "same order?" 80%? 40%? 20%? 5%?
For the same bandwidth? For the same gain?

Without metrics this topic of "Antenna physical size" is a joke.

Bob;

Why don't you make a second antenna. They are easy to make and will
perform as well as the commercial antenna you already have.
When I first got into Amateur radio my transmitting antenna was a 19"
piece of coat hanger. This was bent near one end and soldered to a
antenna connector. This very unglamorious thing was stuck into the back
end of my transmitter and performed very well. You can make something
slightly more attractive for your upstairs receiver for just a few cents.

The 2600 NiMH rechargeable batteries that came with MFJ-259Z are all reading 0 Volts and will not charge in the MFJ-259Z or in my smart charger. I thought that these types of batteries are not effected by discharge memory and yet these seem to be effected by it.

Is there anything I can do to get them working again?

The unit only arrived yesterday from W&S. Its taken long enough for it to arrive with out having to send it back and wait for a replacement from them. It also showed a nice silver shinny coupling antenna attachment in the picture and it came with what looks like an old bent piece of enamelled copper wire bent into a loop that is soldered to a PL259. A bit disappointing really for the money.

> just a coincidence?

Not quite, but close. And averages can not change instantly.

But your phraseology suggests another way to approach
the problem. Let us consider what happens just after
the arrival of the reflected wave. For computational
convenience, we'll use a frequency of 1/360 hertz so
that 1 degree of the wave is one second long.

The reflected wave arrives at 90 seconds (or 90 degrees)
after the source is turned on. If the line is
terminated in 50 ohms, then no reflection arrives and
during the one second between degree 90 and degree 91,
the source resistor dissipates 0.01523 J of energy. The
line also receives 0.01523 J of energy and the source
provides 0.03046 J.
Esource.50[90..91] = 0.03046 J
Ers.50[90..91] = 0.01523 J
Eline.50[90..91] = 0.01523 J
Esource = Ers + Eline
as expected.
Efor = Eline
since Eref is 0.

Now let us examine the case with a 12.5 ohm load and
a non-zero reflected wave.
During the one second between degree 90 and degree 91,
the source resistor dissipation with no reflection

is still 0.01523 J and the imputed reflected wave
provides 99.98477 J for a total of 100.00000 J.

But the source resistor actually absorbs 98.25503 J
in this interval.

Ooooopppps. It does not add up. So the dissipation
in the source resistor went up, but not enough to
account for all of the imputed energy in the
reflected wave. This does not satisfy conservation
of energy, which should be sufficient to kill the
hypothesis.

But Esource = Ers + Eline as expected.
Esource.12.5[90..91] = -1.71451 J
Ers.12.5[90..91] = 98.25503 J
Eline.12.5[90..91] = -99.96954 J
Note that in the interval 90 to 91 degrees, the source
is absorbing energy. This is quite different than what
happens when there is no reflected wave.

You said earlier "Do you think that is just a coincidence?"
It is to be expected that the dissipation in the source
resistor changed; after all, the load conditions changed.
But it is mere happenstance that the average of the
increase in the dissipation is the same as the average
power imputed to the reflected wave; an ideosyncratic
effect of the selection of component values.

> > It is not obvious why you reject this more precise, less
> > misleading description.
>
> Why do you use such unfair ill-willed debating techniques
> based on innuendo and not on facts in evidence?
>
> IMO, our two statements above say the same thing
> with mine being the more precise and detailed.
> I don't reject yours - I just prefer mine.

Authors often do have difficulties detecting when
their words mislead. Excellent authors, and there
are not many, use the feedback from their readers
to adjust their wording to eliminate misleading
prose.

> If the source of the increased dissipation in the
> source resistor is not the reflected energy, exactly
> where did that "extra" energy come from at the exact
> time of arrival of the reflected wave?

Exactly. This is what calls into question the
notion that the reflected wave is transporting
energy. This imputed energy can not be accounted for.

Now the energy that can be accounted for is the
energy that flows in or out of the line. This
energy, along with the energy dissipated in the
source resistor will *always*, no matter how
you slice and dice it, be equal to the energy
being delivered by the source; completely satisfying
the requirements of conservation of energy.

The best that can be said for the imputed power in
the reflected wave is that when it is subtracted
from the imputed power in the forward wave, the
result will be the actual energy flow in the line.
But this is just a tautology; a result from the
very definition of Vforward and Vreflected.

> Hint: Since the only other source of energy in the
> entire system is the reflected wave, any additional
> source would violate the conservation of energy
> principle.

Alternatively, since it turns out that trying to
use this imputed power to calculate the power
dissipated in the source resistor results in a
violation of conservation of energy, this
energy flow imputed to the reflected wave is
a figment. The only thing that is real is the
total energy flow.

Now you have asked repeatedly about the reflection
from the mirror because you are sure that this
is proof of the energy in the reflected wave.

The energy in the light entering your eye is
the total energy; it is not imputed energy of a
wave that is a partial contributor to the total.
If the eye were also a source, such that there
was a Pfor to go along with Pref, then your
question would align with the situation under
discussion. But when the energy flow is only
in one direction, that flow is a total flow
and it definitely contains energy.

To recap, it is when a total flow is
broken into multiple non-zero constituent flows
that energy flow imputed to the constituents
is a dubious concept.

Hi Cecil,

The sheets of roofing are secured together via tek screws that pass
through the overlapping sheets where they are fixed to the truss - so
probably??? Maybe??? No not really.

Consequences?

cheers, Peter.

That describes my aluminum roof.
Never had a problem.
Slope gives a ~50ohm impedance, as mentioned before.

I come up with 141.4v across 50 plus 50 ohms. The current should be 1.414a. Power to each 50 ohm resistor would be 50*1.4142^2 = 200w. For the 1 degree interval of 1 second, that would be 200 joules.

Right? Peak current flows at 90 degrees?

We may be using different sources. My Vs is 141.4cos(wt)
so that between 90 degrees and 91 degrees, my source
voltage is going from 0 to -2.468 V.

And an ooopppps. I actually did the calculations for
a shorted load rather than 12.5 ohms as stated.
With the reflection coefficient of -1 and a 90 degree
delay, the reflected voltage between 90 and 91 degrees
changes from -70.711 V to -70.700 V.

Hoping these details resolve the disparity,

What has not been mentioned much is that AM band broadcast receivers
and FM band receivers are designed to to tune over a fairly wide band
of frequencies; so very difficult to build antenna that will mtach at
all those different 'wavelengths'.

For example; the broadcast band (North America) is roughly 550
kilohertz (that's 545 metres wavelength) to about 1.7 megahertz (about
176 metres). That's 3:1 ratio!

On FM, 88 to 108 megahertz (3.4 to 2.8 metres) the ratio is less but
still cnsiderable at 1.2:1 So again very difficult to design and build
an 'all frequencies' antenna.

For stations designed to receive only one frequncy the antennae can be
constructed for that only; hence the matching can be as optimum as
possible.

3848. through glass coax coupling

Newsgroup: rec.radio.amateur.antenna

Message-ID: <87ve30i4rf.fsf@teufel.hartford-hwp.com>
Source record: 26470

I'm sure a FAQ, but a search on line did not resolve my question.

I need to feed my coax (QRP, 10 meters) out through a pane of glass, and for that I need a through-glass coax coupler (this is not an automotive, but a home window situation).

Most couplers are apparently capacitative. At 10 meters, for example, would I gain much by going to a microstrip coupler instead (whatever that is)?

How good a coupling can I expect with a through-glass coupler? It sounds very lossy, but perhaps not.

What brands of couplers would you recommend, or what is a good source for such couplers?

3849. Suggestions for Intermittent Antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-02 16:52:39 UTC
From: Bob Dixon <dixon.8@osu.edu>
Message-ID: <dixon.8-1710E9.12523902042008@charm.magnus.acs.ohio-state.edu>
Source record: 26471

My 40M beam works only intermittently. Typically under normal conditions, the received signals are weak and the SWR is very high. If I rotate the antenna, it "comes alive" in some directions and works fine for a while, then dies again. In all cases, if I transmit into it with a KW is comes alive and works fine for a while (few minutes) and then dies again. A single dit will fix it. 100W does not do it.

I replaced the coax which runs around the rotator and it made no difference. I just recently learned that a local friend also has an intermittent antenna which can be restored by transmitting a KW into it.

Is this a common problem? is there a generic solution? Any hints would be appreciated. Note that it is not too easy when up on the tower to jiggle things while someone on the ground tries to watch the SWR and shout back and forth. We tried that when we replaced the coax.

Thanks!

Bob W8ERD

>I borrowed some 1800mA and these are charging fine in the MFJ-259, so it
>looks like the
>problem is with the batteries. I have never experienced this with these type
>of batteries before only NiCad's.

What brand and type are the batteries that don't work?

It's possible that you simply received a bunch of batteries that are completely defective (open) or are counterfeit dummies. Seems a bit implausible.

Another possibilty is that the 2600 mAh cells are actually OK, but were delivered to you in a completely-run-down state. That seems plausible... the manufacturer may not have precharged them, or they may have self-discharged in storage after manufacture. The older type of NiMH cells do have a relatively high self-discharge rate, and can go flat after as little as three or four months of storage.

If the batteries read 0 volts, then it's possible that a smart-charger might fail to detect their presence and start charging... I believe that some of the newer NiMH-aware charge-control ICs depend on the detection of _some_ voltage from the cell to detect the cell and start the charge.

Try sticking a few of the cells into an old-style "dumb and slow" NiCd battery charger for a few hours. These are usually fixed-current chargers (100 mA or so) with no battery-detect or charge-cutoff circuits, so they're not a good choice for general use with NiMH cells. They _will_ feed some charge into the cells if the cells aren't entirely open, and should bring the cells up to 1.0 volts or better fairly quickly. After 2-3 hours, take the cells out of the dumb charger, check the open-circuit voltage, and put them in your smart-charger, and see if they are accepted and begin charging. If so, they may be OK. If not, they're probably defective or bogus and you may want to return them to the seller for a refund.

Since an MFJ analyzer is the sort of device that tends to sit around unused for weeks at a time, I think that high-capacity high-self-discharge NiMH cells (e.g. most 2500 or above) are a poor choice. Unless you recharge for an hour or so once a week, you'll probably find them weak or dead when you want use the analyzer.

High-capacity NiCd cells are the traditional choice for this sort of application (and are what I use in my own MFJ). Another possibility is the newer low-self-discharge NiMH cells, such as the Imedions, Eneloops, Hybrios, and Hybrids. These are typically 2000-2100 mAh,

and will hold the majority of their charge for a year or more. If
your MFJ has been modified to charge NiMH properly (e.g. with a good
temperature or zero-delta-V cutoff circuit) they might be a good choice.

In Alaska, we have a lot of Steel, and Galvanized Tin Roofs, and I have
built Antenna Systems using them as RF Grounds, all over the State.
If I have the time, I usually Strip the Ground Braid off a length
of RG-8 Coax and use that to tie the ridge cap and each individual
sheet together, and use that as the Tie point for the RF Ground. That
makes sure that you have electrical bonding for the whole Roof. It
has been my experience that these type systems work well for providing
RF Grounding for Marconi, and End-Feed Longwire Antenna Systems,
especially, considering that the actual Earth up here has very little
Mineralite, and therefor very poor conductivity.

Keith Dysart wrote:
> And averages can not change instantly.

Now there is an assertion that should make you
famous. :-)

I have just had an operation on my eyes. My
prescription will be changing for a couple
of weeks and until then, I will be without
glasses. I have my newsreader characters set
to about 1/2 inch in height so I can see them.
I will be quite handicapped for a couple of
weeks.

> This does not satisfy conservation
> of energy, which should be sufficient to kill the
> hypothesis.

What hypothesis? The scope of my hypothesis is
limited to average power. You have not presented even
one example where my average power hypothesis is
incorrect. I have no hypothesis about instantaneous
power. Any failed hypothesis about instantaneous
power must have been presented by someone else -
it sure wasn't presented by me. I say my GMC
pickup is white. You say it is not white because
the tires are black. Your diversionary argument
is obviously a straw man because you cannot win
the main argument.

Instantaneous power, as Hecht says, is "of limited
utility". IMO, it is irrelevant and certainly far
beyond the scope of my Part 1 article. Please feel
free to write your own article and publish it. Such
an article would, IMO, be a waste of time.

> To recap, it is when a total flow is
> broken into multiple non-zero constituent flows
> that energy flow imputed to the constituents
> is a dubious concept.

Since you have not offered a single average power
example that disagrees with my average power
hypothesis, I guess we will just have to agree to
disagree about that.

You have completely ignored the fact that instantaneous
destructive interference energy is stored for part of
the cycle and then released back into the network as
constructive interference energy 90 degrees later.

I will save your posting and digest it better when
I get my eyesight back along with new glasses.

What you have is an electrical connection that is physically an
electrical
circuit but has a corrosion build up at the joint. A poorly connected
pressure
on the coax is often the cause. Change to a soldered connection and
make
sure the connection is tight. If you have twisted wires on the antenna
put
wire nuts on them.to increase pressure on the joint.
The antenna itself can create similar problems if you have not used a
conductive grease
at telescopic joint connections
Have fun

> MK

Pray tell me then why I am incorrect. You can salvage the
answer from your own mind or even from a book.
If you are going to decry my explanation you must have the reason at
your finger tips.
You heard mention of the Tesla coil earlier as a posters sample with
respect to a particular point.
What the poster did not state was that a Tesla coil is NOT in a state
of equilibrium even tho it may be resonant!
Why else would energy break out from a circuit in the form of a spark
if there was more freedom to travel else where?l

Same goes for the old spark plug system, it is not in equilibrium. So go ahead supply an educated reason
as to why the sparks emminated from the dipole in Quito and why the closed circuit of a quad pushed the
particular problem away. On the other hand give an educated answer to the direction of the three vectors
involved in radiation that Harrison cannot give. You say you have books then go a head with
respect to these two questions that nobody on this group has been able to resolve.
With all the books you say you have then I would agree with you that even a high school drop out
can knock hell out of me with respect to antennas.
Have a happy day and smile
Art.
Ps. When younger I passed the Oxford and Cambridge entrance test on English but old age has taken its toll.

Hello,

a. Anyone have any idea if a receiving Disconne type of antenna is
Polarized horiz. or vert. ?

b. Same question for a Scantenna ?

c. On VHF and UHF scanner freq's, are the (typically vertical, I believe ?)
transmitted polarizations from Fire and PD transmitters usually maintained
over distances of, e.g., 10 miles or so ? Or does "bounce", etc., tend to
totally de-polarize them ?

d. If a receiving signal is well polarized in one direction, say
vertically, how much loss would one expect if the receiving antenna is
oriented such that its preferred olarization is horiz. ?

e.g., for a rubber-duckie scanner antenna ?

Thanks,
Bob

Dave, the batteries are called Supreme Power 2600mA standard charge 14-16 HRS x 260mA, quick charge 4-6 HRS x 550mA. REG USA Made in China.

I am waiting for a friend to bring by his old NiCad charger and I will give it ago. I will let you know how I got on.

For future reference would you have an idea on how long I should charge the batteries for using the MFJ?

I don't know who or how the charger circuit has been modified. I could ask W&S what sort of circuit has been used.

Land mobile and aircraft radios almost invariably
use vertically polarized antennas. That wave
polarization is generally maintained under conditions
of reflection and refraction over short- and long-
distance paths. For polarization rotation to occur
during propagation, the medium generally must be
birefringent (eg: the ionosphere). This rarely occurs
with terrestrial waves.

> d. If a receiving signal is well polarized in

The usual figure one sees bandied about is 20 dB.

> e.g., for a rubber-duckie scanner antenna ?

There's an additional penalty of 20 dB imposed on
any antenna that has the word "duckie" in its name.
;-) ;-) ;-)

I've seen it quoted as "up to 30 dB". That's probably under ideal
(or ideally-bad) conditions, though.

> ;-) ;-) ;-)

Heh. Yeah. Last weekend, my partner-in-repeater-crime and I ran some
simple outdoor-range tests on a few 2-meter beams, using an HP signal
generator and HP spectrum analyzer. We used a quarter-wave whip,
mag-mounted on a sheet of steel, as the reference antenna.

A two-element HB9CV beam was around 8 dB better than the reference
antenna, with a front-to-back ratio of 6-8 dB.

An Elk log-periodic 6-element beam measured out as quite similar to
the HB9CV (but has a lower SWR across the band) - 8 dB up, and about 7
dB front-to-back.

A 3-element Yagi made out of PVC and steel measuring tape segments,
designed for foxhunting, was 9-10 dB up and had about a 20 dB
front-to-back ratio at its deepest null.

Rubber duckies? Ugh. A Yaesu helically-wound duck was around 10 dB
worse than the reference antenna. An RD-9 "high gain" base-loaded
2-meter/440 superflexible antenna was around 12 dB worse than the
reference antenna.

I'd always heard that rubber duckies were actually rubber dummy loads.
Now I've actually seen the results for myself. Yeech.

what brand/model? the 40-2cd has a known problem with the loading coil connections becoming intermittant that gives symptoms just like that. other loading coils, baluns, or matching section connections may do the same thing on other models.

Hmmm. I see various web sites offering that brand, but I don't see
much in the way of comments about their quality (good or bad).

>I am waiting for a friend to bring by his old NiCad charger and I will
>give it ago. I will let you know how I got on.

Please do - I'm curious.

>For future reference would you have an idea on how long I should charge
>the batteries for using the MFJ?

Depends on the charger. In general, a fully-discharged NiMH cell will
need to be "fed" somewhere around 150% of its rated capacity in order
to reach full charge - some of the energy fed into it is dissipated as
heat and doesn't go into rebuilding the electrochemistry. The
"standard charge" recommendations you quoted are feeding the battery
at a rate of .1C (10% of its capacity per hour) for 14-16 hours, so
that's just about right.

If you're using a different charger, you'd need to determine the
amount of current being fed to each cell, divide that into the cell's
rated capacity (to get the time required for 100% capacity delivery),
and then add around 40-50%.

These calculations apply *only* to cells which are fully discharged!
If a cell is partially charged when you start to recharge it, it'll
reach full charge sooner than these calculations indicate... and at
that point the cell starts to heat up pretty rapidly.

Most of the NiMH technology sheets I've read, seem to recommend
charging these batteries at a relatively fast rate (no less than .2C,
with .5C and 1C being common) and using a temperature sensor as the
primary means of figuring out when to turn off the charge.
Zero-delta-V is often used as a secondary method, with a timer being
the final fallback.

>I don't know who or how the charger circuit has been modified. I could
>ask W&S what sort of circuit has been used.

That would be a good idea!

The 259/269 have a simple slow/trickle-charge circuit built in... it's
OK for NiCd cells but isn't ideal for NiMH. It would be very
interesting to know how this was modified for NiMH in the 259Z model.

You may want to use the NiCd charger on them for a few minutes and
then move them to the NiMH charger.

If the rx is for FM only it makes a lot od sense.
The limiter in the FM receiver actually removes AM modulation.

Haines,

Automotive couplers for two metres manage with a 2 inch by 2 inch plate either side of the glass. It could be worth trying 6 inch by 6 inch plates on the domestic window and see what signal level gets out. Reception shouldn't be a problem if you can get 50% or more of your transmission power out through the glass.

You need to get as much capacitance as possible, which means big plates as closely spaced together as possible.

The plates can be formed from aluminum foil taped closely to the window for experimental purposes. Adhesive coated copper sheet or foil can be used once you have found a size and shape that works best for you.

Provided the window is single glazed, you have a chance of getting this to work. If the window is double glazed or has any type of thermal barrier coating, get out the power drill and fix a cable through the wall.

The only advantage that a commercial coupler might have is that the visual asthetics might be a bit better than a home brewed effort.

If the window can be opened, use a bit of thin figure of eight twin cable to bridge across the opening and just shut the window on it. Connect up the coax inside and outside and you're up and running. The bridging cable can be easily replaced if it gets broken by the window opening and shutting. A few inches of twin cable won't mess the overall impedence of the antenna system up too much.

Hi Richard,

Never one to refuse a challenge.
The old speakers were a pair of Celestion Ditton 15XR's with 30 watt per channel rating and a flat sound response output from around 20Hz to 20kHz, 104db at 1 yard driven with 1 watt. The XR stood for extended range indicating that the speaker design had been modified and upgraded from the

original Ditton 15 specifications.
The new speakers I mentioned are a pair of Creative T20's. 14 watts per channel from a built in amp and very nice to listen to. They don't really compare with the Celestions for the smooth mellow sound that only seems to come with wooden cabinets, but for the price they are excellent. Good point about the magnets though. The super high powered magnets, ultra rigid, lightweight fibre glass cones and developments in ported cabinet design have all contributed to the superb performance of the T20's.

Apparently they have been out for a while now, but it was only when I was wandering about in a PC World store that I heard a pair up and running. I was stopped in my tracks by the sound coming out of these tiny devices and spent a good couple of minutes looking for the subwoofer unit that I felt sure was hidden away somewhere. There wasn't a subwoofer and after that, I just knew I had to buy a pair.

I have no connection with Creative and in fact I am a bit annoyed with the company's attitude to (not) providing proper sound card drivers for Windows Vista.

Anyway, just go and check out the web reviews.

Sorry everyone else, but this bit hasn't really got anything at all to do with antennas.

Cheers

Mike

What must be really wonderful is how these speaker manufacturers have not
only managed to change resonant points, but managed to get these very
small systems to move the massive amounts of air needed with the small
speaker systems involved! Oops, sorry, I got sarcastic..

While it is true that we can get better sound from smaller speaker
systems than we have been able to in the past, we have to keep in mind
that those advances are available for the full size systems too. IOW, all
things being equal.....

No new physics are needed.

>When the air breaks down around an antenna it is because the antenna
>is not in a state of equilibrium.

Define equilibrium as it pertains to an antenna. Until you do, it's
fairly hard to comment on the first statement.
If you have corona discharge from an antenna, it's usually due
to sharp points when using wire or a whip with a pointed tip.
Thats why they stick round balls on whips, flagpoles, etc..

>When a dipole is replaced by a quad ala
>a series circuit is replaced by a tank circuit it clearly shows that
>the latter is more efficient.

What clearly shows this?
This is the statement which drew my comment.
The efficiency of a 1/2 WL dipole and a 1 WL loop are so close as
to be almost unmeasurable in the real world.
But you can take this even farther. Almost *any* size dipole
or loop will radiate most all of what is fed to it.
A 1/10 WL whip radiates almost all of the power applied to
it, same as a 1/4 WL, 1/2 WL, or whatever you want to try.
This not not conjecture. This is pretty much written in stone
after many years of testing.
Why you continue to ignore this simple fact boggles my mind.
So your statement is so far from reality I would be amiss
in my "talking head" duties if I did not comment.
Don't take my word for it. Ask anyone you can think of
that has a clue. They will tell you the same thing.

What it going to spoil your "full size performance from a
dinky radiator" picnic is not the radiator and it's abilities to be
an efficient radiator.
It's going to be actually feeding the power to such a small
radiator and not turning a large amount of RF to heat in the
process. No cheating letting the feed line be the antenna..
Look at "small" HF transmitting loops. Do you see any
using 22 gauge wire? I doubt it.
They will be using the fattest or widest strip of material
they can get their hands on.
There are other issues involved also in feeding such an

antenna. Never do these small loops equal the performance
of a full size antenna. They radiate enough to maybe let
you operate, and thats about it.

>This was firmly proven in Quito.Maximum radiation
>efficiency requires equilibrium. Period

Again, the change to quad loops at HCJB was to
avoid the sharp points of the dipoles, yagi's, or
whatever they were using. In the high alitudes of
Quito, HV breakdown at the tips was a serious problem.
The change had absolutely nothing to do with antenna
efficiency.
Not to mention that the whole idea of a loop being
more efficient than a dipole is totally wrong.
And I don't see how equilibrium has anything to
do with it, whatever you might mean by that silly "E"
word.
Anything else you are curious about?
BTW, no grabbing of books were needed to form
this response.
Art

The effective 2M antennas (Antenna Specialists) accomplish the lossless fed
through because the radiator is voltage fed half wave and the interior
coupling unit has a hi-->low Z transformer.
You could do the same at 10M by converting the 50 Ohm feed to a higher
impedance and then down converting outside. The downside is that this will
likely limit your bandwidth a bit.

Basically, one receiver is good. One not so good...
I'd rig up a simple 3 el yagi and point it at the airport.
Then either one will probably work ok. :/
I see the same here with various radios. I have 3-4
that pick up aircraft. 2-3 scanners, and the Icom 706mk2g.
The 706 smokes the scanners as far as sensitivity on
the air bands. The scanners are all fairly cheap radio
shack models, and while they work, you get what you

pay for. All the JRC's are fairly decent radios.
Wouldn't surprise me at all to see one smoke a typical
scanner on VHF.

Most permanent magnet motors will resist rotation if you short the input...
When not driving with a voltage, place a short across the leads. This
essentially has the motor acting as a generator into a dead short, which
makes for significant torque to overcome the subsequent rotational
resistance. Not as good as a wedge (like many commercial rotators) or a
really high gearing ratio (worm and gear or worm and sector), but if
you've already got a reasonable gear reduction it may be all you need...

HI,
I hav horn antenna which is required to be simulated. Its open
mounth has dimensions 36"X27" n short mouth has dimensions 6.5"X3.25".
Its height is 48" n excitation point is 3" away from shorter side i.e.
6.5". Excitation point uses N-type female connector n probe is of
copper of 0.125" in length.
Please give me its simulation result or send me its simulation
sofrware link if u know

>
> What clearly shows this?
Well there is no discharge. This is becaquse that there is a route
of a lesser impedance available

> This is the statement which drew my comment.
> The efficiency of a 1/2 WL dipole and a 1 WL loop are so close as
> to be almost unmeasurable in the real world.
Almost doesn't count when measuring efficiency and in the real world
many CAN tell the difference
> But you can take this even farther. Almost *any* size dipole
> or loop will radiate most all of what is fed to it.
Again you are admitting to lower efficiency when you use the word
"most"

> an efficient radiator.
> It's going to be actually feeding the power to such a small
> radiator and not turning a large amount of RF to heat in the
> process. No cheating letting the feed line be the antenna..

I think you are missing the point here. My antenna has a full wave length of wire
not a fraction there of. So the radiator has the same inductance and capacitance
that one would expect from a full wave antenna spread out in a straight line
where the wire surface is exposed to the atmosphere, so there is no reason
for the energy to circumvent the wire circuit as it must do for a fractional wavelength.

> Look at "small" HF transmitting loops. Do you see any
> using 22 gauge wire? I doubt it.
> They will be using the fattest or widest strip of material
> they can get their hands on.

What you are seeing as representing a loop antenna is a fractional wave length
Often it comes with a HV variable capacitor for tuning.

The loop that I made was a plastic loop with a full wave length of wire wound upon it. No high voltage capacitor needed as it coveres the whole band.
As far as 22 gauge wire being used this is because there is no mechanical stresses
imposed on it as would be for a stretched out radiator. So the main consideration
is to supply enough skin depth since the diameter itself
is not a factor in terms of fusing.current

> There are other issues involved also in feeding such an
> antenna. Never do these small loops equal the performance
> of a full size antenna. They radiate enough to maybe let
> you operate, and thats about it.

If the scource impedance is one that you can match efficiently
then you have at hand a efficient radiator of a wavelength where
the normal loop you are refering to uses a metal loop as the radiator
which is much shorter than a wavelength of wire wound on a plastic loop.

The loop is now a small full wave radiator not a small fractional
small wave antenna

>
> >This was firmly proven in Quito.Maximum radiation

> avoid the sharp points of the dipoles, yagi's, or
> whatever they were using. In the high alitudes of
> Quito, HV breakdown at the tips was a serious problem.
> The change had absolutely nothing to do with antenna
> efficiency.
If the impedance is to high on the antenna compared to
discharging through air to the transmitter ground then that
is a very inefficient antenna

> Not to mention that the whole idea of a loop being
> more efficient than a dipole is totally wrong.
The energy travels easily along the wire circuit without
encountering a high impedance that it is forced to take a circuitous
route thru ground to the transmitter ground. When the energy
is passing thru ground it becomes a loss.

> And I don't see how equilibrium has anything to
> do with it, whatever you might mean by that silly "E"
> word.
If a circuit is not balanced and a fractional wave length long
it is not in equilibrium!. The energy supplied to the radiator
will always encounter a energy wasting impedance in the wire itself if
is not at least a wavelength long, and of the right material
(diamagnetic)
otherwise the energy will seek a route outside the wired circuit which
can only lead to losses. Think of it this way, a fractional wave
length radiator
cannot avoid the energy taking a route thru ground and the ground is a
loss.
Hopefully you now see antennas in a different light. I do urge you to
look up
the tank circuit since it is quite an interesting circuit with its
phase changes
and effective resistances apparently changing without being diverted
from the circuit wire confines. Another place where the books are in
error
is their association with the iron filing magnet experiment at HS
which
forms a magnetic field very different from that formed from aluminum,
copper and other diamagnetic materials. When you pass a time varying
current thru
copper the magnetic field turns at right angles to the radiator axis
and in fact

compliments the electrical field vector (they are not at right
angles)
Now you can see what lifts or ejects the static particles resting on
the surface
because they are repelled instead of bing magnetically atracted
(Static: nearly devoid of energy and of small mass)
. So the EH antennas which supposedly combines the EH fields just
didn't
understand that with a radiator the combination of vectors is already
a given!
I think you also are making a mistake that many books make when
referring to
small antennas instead of referring to ELECTRICALLY small antennas

Thank you very much for that.Fortunately the system appears to be
stable enough
as the antenna and mesh dish is very light and minimul wind
resistance.

A NiMH or NiCd cell reading of zero volts usually indicates an internal short, caused by metallic dendrite growth. If this is the problem with the cells, they won't respond to any ordinary attempt to charge them. It's sometimes possible to "zap" a shorted cell (by discharging a very large capacitor into the cell) to burn out the shorts, but you end up with a cell that has higher than normal self-discharge and a tendency to grow shorts again. So if they don't respond to normal charging, I recommend tossing them and getting some new cells.

If the device has a charger designed for NiMH cells, that is, one that charges at a fairly high rate and properly detects the end of charge, then I highly recommend one of the newer low-self discharge cells such as the Sanyo Eneloop. If it doesn't have a proper NiMH charger and just pumps in a constant current charge without end of charge detection, you should use NiCd cells because they can tolerate that charge regimen much better than NiMH cells can. I've had very good luck with Sanyo and Panasonic NiCd cells. Don't be suckered by inflated capacity claims which the minor brands liberally use. Even with the better brands, the highest capacity cells have historically had more problems with overly fast self discharge and premature cell failure.

The suggestions for a panel to insert into a partially opened window and to close the window on twin lead seem out. It's a steel casement type window that must be fully shut, and even if twin-lead were to get around the edge, it would be sandwiched in steel. I don't own the wall, so even if a hole could be put in it (which it can't), I don't own it.

On the positive side, this is a single pain of ordinary class, and I could make a capacitative coupler over 12" square and still get too near the steel frame. It's a curtained window, and so appearance is not important.

A question. Is this coupling purely capacitative at this frequency (the more surface area the better), or is it somewhat tuned (try different sizes to see what signal level gets out).

An obvious question, how can the coax be connected to the sheets of metal? That is, what happens to the braid? Or could there be two sheets next to each other on both sides of the glass, say one foot square each, with one for the coax center conductor and one for its braid?

> The only advantage that a commercial coupler might have is that the
> visual asthetics might be a bit better than a home brewed effort.

I was hoping to see a commercial coupler to figure out how they are constructed, but so far have seen only one for XP radio, and it is not clear what's up with it.

> likely limit your bandwidth a bit.

Dale, this is interesting, although my initial challenge is just to get capacitative coupling through glass without much attention to the impedance on either side. I hope/assume that at 10 meters, paralel metal sheets under a foot in size will represent just an impedance affecting signal strengh a bit, not something in need of tuning.

When you speak of "radiator", I assume you mean the antenna itself rather than the metal sheet that is inside and radiates through the glass. I'm running a magnetic loop antenna, with an antenna tuner inside the building at the transmitter end of the coax.

==========
Suggest you allow a say 100 mA current to flow through the individual
(new)batteries , monitoring the voltage across the battery.
As soon as the voltage is 1.2 V you can further charge in your automatic
charger.
When fully charged , discharge either in your automatic charger or
manually (with a 12 to 15 Ohms resistor) ,down to
1Volt and recharge. The (new) batteries should then work well.

New NiMH batteries often need a few manually imposed charging
/discharging cycles before working properly.

Good Luck

Dear kalpraj.m

Go to your school's library. Find books on antennas. Kraus' book (any edition) is good choice. Turn to the chapter on horn antennas, which is Chapter 9 in Kraus' Antennas, third edition. Study material.

Good studies, Mac N8TT

I am sorry Keith, but I still can not duplicate your work. I wonder if the difference is in how we each apply the recharge voltage to the transmission line.

I redid my table showing the power in the source and reflected waves. I now have the power to resistor Rs coming from voltage agreeing with the expected power calculated from current.

The table can be found at
http://www.fairpoint.net/~rsparks/Smooth%20Power%20Reflection.pdf.

Pan tilt and revolve now working perfectly. Antenna does not exceed
3.2 to 1 from
!.8 upto 170 Mhz just like a log periodic tho it can be adjusted at
any frequency
if I felt the need. Today I will be checking out the TV stations and
tonight
I will get on the air without the amplifier. Life is good
Art

This antenna is probably going to have to come down for a look-see. I
would suspect something very near the area closest to the mast, but
those coils are a suspect too.

Running high power into the antenna might fix it, or might burn a coil
or other part up. I guess the rationale was to heat up an intermittent
connection, and "weld" it back together. Hoo boy, I'd pass on that.

Setting the antenna down will allow you to do some maintenance on the
whole thing. If you have one intermittent, problems can show up in other
places too, so its time to bite the bullet. Certainly not pleasant with
a 40 meter beam.

From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <a86av35jjnv4crg0n9cffpi83k3pj98kij@4ax.com>
Source record: 26363

I have been given a W2AU balun. It is an older one with no markings other than W2AU BALUN on it. I am not sure which model it is, 1:1 or 4:1, but I am guessing it is 4:1.

The balun has a metal bar that goes from the ground screw of the SO-239 connector to the support eyelet on the top of the balun.

It is 6 inches long with about 1.5 inch diameter tubing. It has three eyelets, one on top and one on each side of the top for the dipole wires.

Can anyone confirm what I have here?

thanks

Source record: 26365

I can't say whether it's 4:1 or 1:1, but it fits the description of a 1:1 W2AU balun I got long ago. I think they might have changed the design somewhere along the line, but the one I have is a voltage balun. A 1:1 voltage balun measures a short circuit across the two input terminals or two output terminals; a 1:1 current balun will read open. If it's a 4:1, it's very likely a voltage balun, but both voltage and current 4:1 baluns will show a DC short across the terminals. The only way I know of to determine whether it's a 1:1 or 4:1 is either to use something like an antenna analyzer, or connect the output to a 50 ohm dummy load and look at the SWR at the input side. If it's a 4:1 balun, the SWR will probably be at least 4:1, and likely higher.

Hello,

Why not using inductive coupling? You can get reasonable coupling as
wires are just mm away from eachother, so you don't need high Q factor
circuit.
Matching indoor only is possible (so you don't need matching outside
to interface to 50 Ohm coaxial cable).

Didn't occur to me. Are you suggesting a couple coils sharing an axis,
one just inside the window and the other outside? Would the two coils
simply be designed for a 50-ohm impedance at, say, 10 meters?

I can imagine wrapping a 50-ohm coil on pvc, and inserting it into a
larger diameter pvc that is capped and which has a coax connector passing
through it. and the whole attached to the glass with silicone
adhesive. One on either side of the glass.

> Matching indoor only is possible (so you don't need matching outside

Not sure of your point. It seems I need to match outside.

Another problem just occurred to me. I'll use a MFJ magnetic loop, and
its tuner, if I recall, depends on an uninterrupted electical connection
through the coax. If so, I'm stuck.

Hello,

I was thinking of just 1 turn windings glued on the window of about
D=10'' (correctly aligned), in combination with a two trimmer
capacitor match (from which one can probably be a fixed value after
experimenting).

When you would do matching both inside and outside you can get a
broader response. Window glass is just about 0.15'' thick, so I think
a single match (inside) would have sufficient bandwidth (especially
when you would use foil/strip material for the two single turn
windings).

I think that at 91 degrees, the sign of the returning wave should be positive, not negative. Thus, it should be +1.234v. My reasoning is that the voltage from the line side of the resistor adds to the voltage from the source side of the resistor, but in this case it takes a little longer to get around the loop. The 90 degrees is timing, the lead edge of the wave is not reversed by turning the corner at what we call the short.

Another way of thinking about it is that if the transmission line was shorter, the added voltage to the resistor from the line side would arrive even earlier, and add. If the line were zero length, there would be no question but that the voltage would add.

Lastly, your current peaks at 135 degrees, not 45 degrees, which should be the delay.

It is interesting to notice that the current is delayed 45 degrees, but the voltage is delayed 90 degrees. It is as if the current does not take the entire trip around the loop, but the voltage does. The current apparently travels an average of half the distance around the loop.

I know that the convention for calculating the reflection coefficient is to make it negative for a shorted transmission line. The negative sign makes sense because the voltages at the short cancel so we have a zero voltage across the short. That convention sure messes up our spread sheet calculations however.

This circuit has a reflection at the 50 ohm resistor because the impedance transitions from 50 ohms to 100 ohms, then back to 50 ohms.

Haines,

The versions I used years ago relied purely on capacitive coupling. The braid was broken and only the centre lead of the coax was connected to the plates. The earth return was via the automobile chassis for vehicle use, or via earth connections for domestic use. The metal frame of the window might work if you have any means of getting a good connection, otherwise you will need some form of reliable (low impedence) earth connection inside and outside the building for the system to work properly.

The coupling through the glass should be purely capacitive although some inductance effects will inevitably be introduced due to the size of the plates.

As an alternative you might consider making up two matched tuned circuits (coil and capacitor) set for the 10 metre band and try inductively coupling the coils through the glass. To my mind that would be smaller and easier to set up without the need to worry about earth feeds. A kind of through glass balun if you like. Obviously you will need to keep a reasonable distance away from the metal window frame, but a couple of turns of wire and a couple of capacitors may be all you need.

Haines,

Just read the other postings about inductive coupling and I think that would be the best way to go with a standard wire antenna like a half wave dipole, vertical, etc.

I can't see any way of getting a magnetic loop antenna to work because you need a direct DC path for power and tuning commands from the tuning unit to the loop.

Might be better to put your ingenuity to better use by finding somewhere hidden to run a thin bit of coax through the wall. Behind a switch plate, power socket, joint fillet, alongside a pipe. There must be somewhere to put a 1/4 inch hole that can be concealed later? For QRP work, you might get away with a short through wall length of really thin coax, the 1/8 inch stuff used to connect signal assemblies inside equipment.

If you are really brave, a masonry drill at high speed will cut through glass with a bit of soapy water acting as a lubricant. Take your time and try and brace the other side with a wooden block or elses a big bullseye chip will be thrown out when the drill breaks through. Fill the hole with transparent quick set epoxy when it is no longer needed.

> I think that at 91 degrees, the sign of the returning wave should be positive, not
negative. Thus, it should be +1.234v. My reasoning is that the voltage from the line side
of the resistor adds to the voltage from the source side of the resistor, but in this case
it takes a little longer to get around the loop. The 90 degrees is timing, the lead edge
of the wave is not reversed by turning the corner at what we call the short.

I do believe that -1.234 is correct. The reflection coefficient is -1,
so at the
short, Vr(t) is always equal to -Vf(t), which, when summed, give a
Vtot(t) of 0
which is what is expected at a short. Vr.g(t) is delayed by 90 degrees
from
Vf.g(t) so at 91 degrees, we should expect Vr.g(91) to be (-1 *
Vf.g(1)) or
-1.234. This is also how the spreadsheet computes it.

> Another way of thinking about it is that if the transmission line was shorter, the added
voltage to the resistor from the line side would arrive even earlier, and add. If the line
were zero length, there would be no question but that the voltage would add.

Vg(t) is the voltage across the line, so Vg(t) is the sum of Vf.g(t)
and Vr.g(t),

recalling that Vtot = Vf + Vr.

And
Vrs(t) = Vs(t) - Vg(t)
Since Vf.g(t) = Vs(t)/2, and Vg(t) = Vf.g(t) + Vr.g(t) we have, by
substitution,
Vrs(t) = 2 * Vf.g(t) - Vf - Vr.g(t)
= Vf.g(t) - Vr.g(t)

> Lastly, your current peaks at 135 degrees, not 45 degrees, which should be the delay.
>
> It is interesting to notice that the current is delayed 45 degrees, but the voltage is delayed 90 degrees. It is as if the current does not take the entire trip around the loop, but the voltage does. The current apparently travels an average of half the distance around the loop.

Be careful if you are comparing things before and after the 90 degree
point. At 90
degrees, the circuit conditions change dramatically.

At the entrance to the line, Ig is delayed 90 degrees from Vg which is
to be expected
since the line is behaving as a pure inductor from any time after 90
degrees. Before
that the line is behaving as a resistance.

At the resistor, the offset is only half this because the resistor and
the line have
the same magnitude of impedance.

> I know that the convention for calculating the reflection coefficient is to make it negative for a shorted transmission line. The negative sign makes sense because the voltages at the short cancel so we have a zero voltage across the short. That convention sure messes up our spread sheet calculations however.

One does have to be careful to treat the signs consistently. In this
sheet, the convention
is that flows (current and energy) to the right (assuming the load is
to the right) are
positive. Some conventions use positive to mean flows to the right for
the forward wave
and flows to the left for the reflected wave.

On this sheet, Vtot = Vf+Vr, Itot=If+Ir and Ptot=Pf+Pr.
I hope no gremlins snuck in.

It seems to me that this circuit is quite different.
There is a reflection where the left TL connects
to the 50 ohm resistor. There is a reflection when
the reflected wave on the left TL arrives back at the
source and there is a reflection when the reflected
wave on the right TL hits the 50 ohm resistor.

This circuit takes an infinitely long time to settle.
The previous circuit only had a reflection at the load
and settled after one round trip.

Quite different.

I had a problem like that with a little Yagi for 10M I bought at a
hamfest. The Aluminum rod for the gamma match was riveted to the coax
connector. Repair was to replace the Al tube with a brass one and a
new connector was soldered to the tube.

> plates.

You'll have a considerable amount of inductance for another reason if you follow this approach.

Consider what happens when you separate the two conductors of the coax as Mike suggests. One conductor continues more-or-less directly through the glass. The other conductor becomes the "ground" path from wherever the current leaves the inside of the coax shield on one side of the glass to where it again enters on the other side. These are the two conductors of a transmission line which you've inserted in series with your normal line. If you'll do a little rough calculating, you'll find that this line has a much higher impedance than 50 ohms. So, if electrically short, its effect will be that of a series inductance. If it's not so short, the impedance transformation will be a lot more interesting. Another thing that happens is that the length of the "ground" conductor is greater than the length of the center conductor. This will probably give rise to common mode currents, which will involve the outside of the coax in the active feedline.

> As an alternative you might consider making up two matched tuned

> a couple of turns of wire and a couple of capacitors may be all you need.

That might have a better chance of producing a smaller disturbance to the whole feed system. If you use direct capacitive coupling through the glass, however, you should remember that you have two conductors to deal

with -- calling one "ground" doesn't give it magic properties. I'd use two coupling plates, one for each conductor, as close together as possible. A bit of intentional shunt capacitance would help compensate for the inevitable series inductance which would be created by even that setup.

OK, I see now. You reversed the sign to calculate Vrs so once I get to the Vrs column, we are the same. You used the -1 reversal to calculate Vg, but plus one to calculate Vrs.

No, it's admitting that no real antenna will radiate 100% of the
power fed to it. Has nothing to do with a comparison of the
various types.

So? From it's claimed performance, it's working as a
great dummy load.
You say it requires no matching to coax, and
covers the whole 160m band..
This simple description tells me your antenna is a
poor radiator of RF. It shows all the qualities of a
air cooled dummy load.
A truly efficient antenna of such a small size would
require matching to the feedline, would be quite high Q,
and the bandwidth would be very narrow.
So narrow as to possibly restrict the audio quality
of the average 2.5- 3 kc transmitter width .. :(
You can actually hear the restriction on the air.
I've noticed this many times when people try
very small high Q antennas on that band..

This is reciprical, and will be noticed on receive
also if you A/B between a full size antenna vs
the small version.

No, it's a small antenna, coil loaded with many feet of 22 gauge
wire. In fact, the antenna is pretty much all coil.
Not too much different than a wound loopstick used for MW.
Their virtues as efficient radiators of RF are about nil.. :(

> If the impedance is to high on the antenna compared to
> discharging through air to the transmitter ground then that
> is a very inefficient antenna

No. It has nothing to do with antenna efficiency.
Antenna efficiency is reciprical from receive to
transmit.
It's like me taking a nearly fully efficient dipole
and running it through a bunch of wet tree branches
with poor insulators, and then running high power.
An antenna that is truly inefficient will be inefficient
on both transmit and receive.
Obviously in the case of the dipole, this is not the
case. When receiving only, I bet it works just fine.

>
> > Not to mention that the whole idea of a loop being

> since Eref is 0.

OK, Power at the source is found from (V^2)/50 = 0.03046w. Another way to figure the power to the source would be by using the voltage and current through the source. Using current and voltage, the power at time 91 degrees of the reflected wave is 1.234v*1.43868a= 1.775w. Over one second integrated, the energy should be 1.775 J.

> Now let us examine the case with a 12.5 ohm load and

>
> But the source resistor actually absorbs 98.25503 J
> in this interval.

100 - 1.775 = 98.225 J

The apparent impedance of the reflect wave has changed from 50 ohms to 0.8577 ohms.

There is still a confusion between what power comes from where at time 91 degrees, at least partly coming from how Vg is used. Or maybe the confusion is because we are mixing a circuit with a shorted line with calculations from a line with a 12.5 ohm load.

>
> ...Keith

The power seems pretty well accounted for degree by degree so far as I can see right now.

I think your spread sheet would be easier to follow if the reflected power beginning at 91 degrees was positive, like adding batteries in series. That is what happens and there is no reversal of voltage when examined from the perspective of the resistor. There is only a delay in time of connection to the voltage source on the line side of the resistor.

>> I was hoping to see a commercial coupler to figure out how they are
>> constructed, but so far have seen only one for XP radio, and it is not
>> clear what's up with it.

If by commercial couplers you mean the units for through glass antennas, then the ones that I have taken apart consisted of a parallel tuned circuit with the coax inner tapped a little way up the coil and the braid connected to the cold end of the coil. The 'hot' end of the tuned circuit was connected to the coupling plate. The antenna just had a coupling plate. Of course it worked by virtue of the approx 1/2 wave whip having a high impedance at the base, so the required value of coupling capacitance was not extremely high.

I measured the terminals. they are short together and short to the
coax shield and short to the coax center.

Thanks for the input.
Buck

```

>
> OK, Power at the source is found from (V^2)/50 = 0.03046w.

Not quite.

>Another way to figure the power to the source would be by using the voltage and current through the source.

This is how I did it.

Taking Esource.50[90..91] = 0.03046 J as an example ...

Psource.50[90] = V * I
= 0.000000 * 0.000000
= 0 W
Psource.50[91] = -2.468143 * -0.024681
= 0.060917 W

Using the trapezoid rule for numerical integration,
Esource.50[90..91] = ((Psource.50[90]+Psource.50[91])/2) * interval
= ((0+0.060917)/2)*1
= 0.030459 J

The other powers and energies in the spreadsheet are computed similarly.

There was an error in the computation of the 'delta's; the sign was wrong.
The spreadsheet available at http://keith.dysart.googlepages.com/radio6 has
now been corrected. (And, for Cecil, this spreadsheet no longer has macros
so it may be downloadable.)

To use this spreadsheet to compute my numbers above, set the formulae
for Vr.g and Ir.g in the rows for degrees 90 and 91 to zero.

> Using current and voltage, the power at time 91 degrees of the reflected wave is 1.234v*1.43868a= 1.775w. Over one second integrated, the energy should be 1.775 J.

I could not match to the above data to any rows, so I can't comment. But
perhaps the explanation above will correct the discrepancy.

> > Now let us examine the case with a 12.5 ohm load and
> > a non-zero reflected wave.

This was an ooooopppps. The spreadsheet actually calculates
for a shorted load.

> > During the one second between degree 90 and degree 91,

>

> > But the source resistor actually absorbs 98.25503 J
> > in this interval.
>
> 100 - 1.775 = 98.225 J

I computed 98.25503 J from applying the trapezoid rule for
numerical integration of the power in the source resistor
at 90 degrees and 91 degrees.

I am not sure where you obtained 1.775 J.

> The apparent impedance of the reflect wave has changed from 50 ohms to 0.8577 ohms.
>
> There is still a confusion between what power comes from where at time 91 degrees, at least partly coming from how Vg is used. Or maybe the confusion is because we are mixing a circuit with a shorted line with calculations from a line with a 12.5 ohm load.

I do not think the latter is happening. If you want to see
the results for a 12.5 ohm load, set the Reflection Coefficient
cell in row 1 to -0.6.

> > ...Keith
>
> The power seems pretty well accounted for degree by degree so far as I can see right now.

>
> I think your spread sheet would be easier to follow if the reflected power beginning at 91 degrees was positive, like adding batteries in series. That is what happens and there is no reversal of voltage when examined from the perspective of the resistor. There is only a delay in time of connection to the voltage source on the line side of the resistor.

When I wrote my original spreadsheet I had to decide which convention to
use and settled on positive flow meant towards the load. Care is certainly
needed in some of the computations. Choosing the other convention would
have meant that care would be needed in a different set of computations.
So I am not sure it would be less confusing, though it would be different.

When using superposition, one has to pick a reference voltage and current
direction for each component and then add or subtract the contributing
voltage or current depending on whether it is in the reference direction
or against the reference direction. Mistakes and confusion with relation
to the signs are not uncommon. Careful choice of reference directions will
sometimes help, but mostly it simply leads to some other voltage or
current that needs to be subtracted instead of added.

please do enlighten us, art has failed miserably in that. i would love to
find out his antenna works as good as a full size half wave dipole and only
had to be tilted and turned on a tiny rotor... sure would be easier to
maintain than my current aluminum farm.

I've had the same set of NIMH 2100 maH Energizer cells in my 259B for over 3 years. I have had them on the internal charger 24x7, except when in use. I have had no trouble with the batteries overcharging with the internal charger in the 259B. (obviously, or I would have cooked them a long time ago).

One thing I've learned about NIMH batteries...they don't sit well. They do wonderfully if kept trickle charged, but if let to sit, they will self-discharge in less than two weeks. (at least for digital camera purposes)I've observed this on three different "sets" of NIMH AA batteries. All act the same way. Two weeks of sitting and they will only operate the camera a very short time. Left in the charger and put directly into service I can shoot well over 75 pictures in a row with no difficulty.

I must apologize for starting a thread that I realized would be for me a dead end. I've not used a magnetic loop before and so easily forgot about the need for a direct DC connection. However, the thread was interesting and hopefully worthwhile.

> Might be better to put your ingenuity to better use

Yes. Options are limited because I'm at the eighth story of a steel high-rise, and the enamled metal outside surface material doesn't lend itself to drilling. In any case, I don't own it and wouldn't feel right about destroying property not mine. The window is a casement window, and I'm now thinking of leaving it permanently ajar and gluing (silicone) on the inside frame a piece of plexiglass with a coax feedthrough. That way I can have light from the window, protection from the elements and not destroy anything. Ultimately it can be removed when necessary.

I thought I would share with you my readings on the 160 M band
They are in order as follows Freq, resistance, reactance swr

1.8 105 0 2.1
1.81 105 0 2.0
1.82 105 0 2.0
1.83 105 0 2.0
1.84 102 0 2.0
1.85 98 0 1.9
1.86 92 0 1.8
1.87 88 6 1.7
1.88 83 7 1.7
1.89 84 8 1.7
1.9 81 12 1.6
1.91 78 13 1.6
1.92 75 12 1.5
1.93 72 13 1.5
1.94 68 11 1.4
1.95 67 10 1.4
1.96 66 10 1.3
1.97 64 9 1.3
1.98 62 9 1.3
1.99 62 9 1.3
2.0 62 7 1.2
The above figures are obtained by ensuring no external inductance and
capacitances
were introduced to the intrinsic radiation circuit during assembly.
As one would expect, the above figures would represent the features
through out the frequency range
Impedance values mainly resistance will change according to the point
of jumper connection of wire supplied.
This allows for lossless matching to the drive circuit regardles of

its impedance value.
Those you are familiar with antennas will see that the above figures
in no way
represent those of a dummy load
'The above figures show an excellent match to 75 ohm cable. Thge
figures were taken with a
mfj 259b which is designed for 50 ohm cables.

> perhaps the explanation above will correct the discrepancy.
>
I took a look at your revised spreadsheet entitled "Reflected45degrees-1.xls". Using the numbers from row 94 (91 degrees), the voltage developed at the source would be Vs = -2.468143v. The current folowing through the source would be found from Ig which is

1.389317a in todays version of the spreadsheet (it was 1.439a previously). The power flowing INTO the source is 2.468143* 1.389317 = 3.429032w. This is the power Ps found in Column 11.

This returning power is all from the reflected wave. The source is acting like a resistor with an impedance of 2.468143/1.389317 = 1.776 ohms. As a result, the returning reflection does not truely see 50 ohms but sees 50 + 1.776 = 51.776 ohms. Of course the result is a another reflection. Is this the idea you were trying to communicate Cecil?

To me, this is destructive interference at work, so all the power in the reflected wave does not simply disappear into the resistor Rs on the instant basis.

Yes. I don't want to force my conventions onto you, so I am trying to understand yours while insisting that the answers from each convention must be the same. I think we both agree that the reflections are carrying power now.

Sure, but there are "laws of physics" which determine the limits, at
some level. No materials with negative conductivity, for instance.

And, by "realizable" here, I mean practical, and a bit beyond. If one's
new and novel widget requires a 30 Tesla magnetic field, that's within
the laws of physics, but somewhat challenging to produce in a practical
sense.

Where you're basically defining "efficiency" as power radiated into the far field in a desired direction vs power into the feedline. That's a fair definition for most amateur applications, if not necessarily defensible in a rigorous analysis. Certainly, if you had two 40m band antennas that were 3 meters across, and one produced a far field that was twice that produced by the other, with the same transmitter power, you'd be justified in saying the first antenna was more efficient than the second, even if neither were particularly efficient in an absolute sense (i.e. 2% vs 1% is a big jump in practical terms).

> To be more specific, I was reffering to such designs that reduce the
> scale of antennas in at least one axis:
> http://adsabs.harvard.edu/abs/2004ITAP...52.1945P

This is an interesting paper.. I note that they use MoM to evaluate the performance. It's a special case of a general class of antennas where you have lots of little pieces that can be reconfigured by frequency selective traps or rf switches to achieve wide feedpoint match bandwidth in a small package. To a certain extent, the SteppIR is also in this same class. The thing where you hook multiple hamstick loaded elements onto one base is also similar. This paper addresses a moderately systematic way to generate candidate physical layouts. Others have done things like rectangular or hexagonal grids of wires or metallic patches.

> http://ctd.grc.nasa.gov/organization/branches/amosb/RCA_RESEARCH/RESEARCH_mini-antennas.
htm

A clever use of antenna layout to get multiband performance in a small package. The small comes from fairly traditional approaches(i.e. dielectric medium, bent and folded elements). I note that they don't claim that it's comparable in efficiency to a full size antenna for the same bands.

The antenna literature of the last 10 years is FULL of various and sundry schemes for bending wires and brushes in one way or another (mostly enabled by cheap computation to see how well it will work, before fabricating a prototype). Check the IEEE Transactions on Antennas and Propagation.

Terminate it with 50 Ohms and put it on an antenna analyzer- if it reads a
low VSWR, it's 1:1. If not, try 200 Ohms- if that reads low then it's 4:1.

I had a problem like that with a little Yagi for 10M I bought at a
hamfest. The Aluminum rod for the gamma match was riveted to the coax
connector. Repair was to replace the Al tube with a brass one and a
new connector was soldered to the tube.

Jimmie

About the same here with a CushCraft 2m beam. Very intermittent. The SO239
shell was supposed to make contact by virtue of being screwed into an
aluminum angle iron. It didn't. Replaced the SO239.

HOWEVER, if you will look at the Antenna Design for a AM Broadcast
Receiver, using a Ferrite Loop Antenna, you WILL notice that the
Loop IS Tuned to the specific part of the band that the receiver is
being tuned to, by Linked Ganged Variable Capacitors, in the Receivers
Frontend. These designs have been around for MANY years, (1940's anyway)
and are a very mature technology.

If you are going to do it this way, I might suggest you use weather stripping (for doors, etc.) instead of Silicone sealer. It comes in a variety of thicknesses.... should provide a good seal for your slightly ajar window, easily allow some RG-8X type coax through, and be a lot easier to remove than the silicone in the future. Also, will still allow you to open your window if need be ... just a thought.

Good to know, thanks! Possibly the trickle charge is of a low enough
rate that the cells do not overcharge much and overheat. Heat is the
enemy of service life.

According to the battery-manufacturer literature I've read, NiMH cells
tend to have poor "charge acceptance" when trickle-charged at very low
rates. If you try to charge them at a rate of, say, .01C (20 mA, for
a 2000 mAh cell), almost none of this energy actually recharges the
cell - essentially all of it turns into heat.

One manufacturer's writeup I've read says that if it's necessary to
trickle-charge the cells to combat self-discharge, it's best done
through a periodic pulse-charging technique. Pulses of current in the
range of .05C through 1C, lasting for .1 to 60 seconds, are suggested,
with the time between pulses set so that the average rate of charge
delivered is around .02C per day. This is enough to combat
self-discharge, without overcharging.

>directly into service I can shoot well over 75 pictures in a row with no
>difficulty.

High self-discharge rates are indeed an issue with the older NiMH
formulas (which account for most of the higher-capacity cells on the
market).

There seems to be a very real tradeoff between capacity and
self-discharge rate... it's a result of the different metal-hydride
alloy formulas used.

The new-generation "ultra-low self discharge" batteries are quite a
bit better in this regard. The Sanyo Eneloops and similar types are
billed as losing no more than around 10% of their total charge after a
month of storage, and still retaining as much as 60% after a year.

The price you pay for the longer holding time, is a reduced maximum capacity (typically 2000-2100 mAh for an AA, as opposed to 2500-2700 for the ultra-high-capacity type).

Many reports indicate that new NiMH cells, and older ones which have been sitting around unused for some time will exhibit reduced capacity, until they've been fully charged and discharged once or twice.

What I am trying to communicate is that the distributed network model is closer to Maxwell's equations that is the lumped circuit model. If the lumped circuit model disagrees with the distributed network model, then it is wrong.

Steady-state conditions are identical whether the ideal transmission line is zero wavelength or one wavelength. If adding one wavelength of ideal transmission between the source voltage and the source resistance changes steady-state conditions in Keith's mind, then there is something wrong in Keith's mind.

> To me, this is destructive interference at work, so all the

power in the reflected wave does not simply disappear into the

resistor Rs on the instant basis.

90 degrees later, an exactly equal magnitude of constructive interference exists so it is obvious that the constructive interference energy has been delayed by 90 degrees from the destructive interference energy.

One advantage of moving the source voltage one wavelength away from the source resistor is that it is impossible for the source to respond instantaneously to the requirements of the source resistor thus making the energy flow easier to track. (I'll be glad when I get my sight back so I can read my calculator.)

This was true until a short while ago, but no longer is. A new chemistry is now being used for some NiMH cells which greatly reduces the self-discharge rate. Some of the more popular brands are Sanyo's Eneloop, Rayovac's Hybrid, and Sony's Cycle Energy, but there's a growing number of others. A bit of web searching will bring a great deal more information about this. "Low self discharge NiMH" is a good search string to start with.

So far, the LSD cells have a bit lower capacity than the very highest capacity conventional cells, with 2000 mAh typical for AA and 800 mAh for AAA. But they have almost as much capacity after sitting for an extended time. And the Eneloops, in particular, typically have a slightly higher voltage under discharge, and hold up very well under high discharge rates. They're very good cells -- I use them almost exclusively now.

One manufacturer's data writeup (for the Twicell batteries) says "The
amount of electricity which a [NiMH] battery loses through
self-discharge at 40 degrees C in one day following full charge is
approximately 5% of the rated capacity."

If it lost this same percentage of its total charge every day, the
battery would be completely self-discharged in about three weeks.

If it lost 5% of its current charge level per day, it'd be down to 50%
charge in a couple of weeks, maybe to 25% at the end of a month.

Even if the self-discharge rate is as low as 2% per day, you'd find
them with little charge remaining after a couple of months.

The high-capacity, fast-self-discharging NiMH cells seem to be a
reasonable choice for certain application - those in which you expect
to drain 'em within a few days of use, and will need to recharge them
regularly in any case. Photo-flash applications, or listen-and-talk
applications in a portable radio, or that sort of thing.

They're a poor choice for occasional-use or standby applications.

If you're using your MFJ-259 for several hours per week, standard 2600
NiMH cells may be a good choice. If you use the analyzer only
occasionally, I think you'll be happier with either NiCd, or
low-self-discharge 2000/2100 NiMH.

I've seen light bulbs act the same way
when rf was fed to them.
How many people do you know that use a light
bulb as an antenna?
I used one as a dummy load when I was a novice.

It was enlightening, I have to admit that... :/

Couldn't have been that great then.

Look up G5RV and you will find plans till the cows come home, a life
history, and all the lore that could fill a library - and it isn't all
that great either.

>
> I took a look at your revised spreadsheet entitled "Reflected45degrees-1.xls". Using the numbers from row 94 (91 degrees), the voltage developed at the source would be Vs = -2.468143v. The current folowing through the source would be found from Ig which is 1.389317a in todays version of the spreadsheet (it was 1.439a previously). The power flowing INTO the source is 2.468143* 1.389317 = 3.429032w. This is the power Ps found in Column 11.
>
> This returning power is all from the reflected wave.

I would not say this. The power *is* from the line, but this is Pg,
and it satisfies
the equation
Ps(t) = Prs(t) + Pg(t)

The imputed power in the reflected wave is Pr.g(t) and is equal to
-99.969541 W, at
91 degrees. This can not be accounted for in any combination of Ps(91)
(-3.429023 W)
and Prs(91) (96.510050 W). And recall that expressing Cecil's claim
using instantaneous
powers requires that the imputed reflected power be accounted for in
the source
resistor, and not the source. This is column 26 and would require that
Prs(91) equal
100 W (which it does not).

> The source is acting like a resistor with an impedance of 2.468143/1.389317 = 1.776 ohms.

This is not a good way to describe the source. The ratio of the
voltage to the current
is 1.776 but this is not a resistor since if circuit conditions were
to change, the
voltage would stay the same while the current could take on any value;
this being
the definition of a voltage source. Since the voltage does not change
when the current
does, deltaV/deltaI is always 0 so the voltage source is more properly
described as
having an impedance of 0.

> As a result, the returning reflection does not truely see 50 ohms but sees 50 + 1.776 = 51.776 ohms.

The returning reflection is affectively a change in the circuit
conditions. Using
the source impedance of 0 plus the 50 ohm resistor means the
reflection sees 50
ohms, so there is no reflection.

Using your approach of computing a resistance from the instantaneous
voltage and
current yeilds a constantly changing resistance. The reflection would
alter this
computed resistance. This change in resistance would then alter the
reflection
which would change the resistance. Would the answer converge?

The only approach that works is to use the conventional approach of
considering
that a voltage source has an impedance of 0.

> Of course the result is a another reflection. Is this the idea you were trying to
communicate Cecil?
>
> To me, this is destructive interference at work, so all the power in the reflected wave
does not simply disappear into the resistor Rs on the instant basis.

I agree with latter, but not for the reason expressed. Rather, because
the imputed
power of the reflected wave is a dubious concept. This being because
it is impossible
to account for this power.

Not I. Not until the imputed power can be accounted for.

There was an 'if' there, wasn't there? Do you think
the 'if' is satisfied? Or not? The rest is useless
without knowing.

You still have to explain where this destructive energy is stored
for those 90 degrees. Please identify the element and its energy
flow as a function of time.

> One advantage of moving the source voltage one wavelength
> away from the source resistor is that it is impossible for
> the source to respond instantaneously

You have previously claimed that the steady-state conditions
are the same (which I agree), but now you have moved to discussing
transients, for which the behaviour is quite different.

If you want to claim similarity, then you need to allow the circuit to settle to steady state after any change. Instantaneous response is not required if the analysis is only steady-state.

If you wish to study transient responses, then the circuits do not behave similarly.

==========
NiCad and NiMH batteries (usually having a capacity exceeding 400mAh)
which need to perform at all times I normally charge constantly with 10
mA when not in use. This trickle charge level keeps them in good condition.
I have a Wahl ISOTIP 2.4 V soldering iron which in this way is always
available. When in use I switch the charging current to 300 mA

Keith Dysart wrote:
> Please expand on what it tells us "about what is wrong
> with the analysis so far".

You have not been able to tell where the instantaneous
reflected energy goes. This new example should help
you solve your problem. If your steady-state equations
for the new example are not identical to the steady-
state equations for the previous example, then something
is wrong with your previous analysis. IMO, something
is obviously wrong with your previous analysis since
it requires reflected waves to contain something other
than ExH joules/sec, a violation of the laws of EM
wave physics.

feedline1 feedline2
source---1WL 50 ohm---Rs---1WL 50 ohm---+j50

The beauty of this example is that conditions at
the source resistor, Rs, are isolated from any
source of energy other than the ExH forward wave
energy in feedline1 and the ExH reflected wave
energy in feedline2. That's all the energy there
is available at Rs and that energy cannot be denied.

> resistor, and not the source.

Keith, I hope that Roger knows you are uttering falsehoods
about what I have said.

I. My Part 1 claim applies *ONLY* to a zero interference
precondition. Your example contains interference. Therefore,
my claim does NOT apply to your example. Examples containing
interference are yet to be covered in Parts 2 and 3 of
my series of articles. I am going to state my claims once
again.

1. If zero interference exists at the source resistor, all of
the reflected energy is dissipated in the source resistor.
Your example does NOT contain zero interference.

2. If interference exists at the source resistor, the energy
associated with the interference flows to/from the source
and/or to/from the load. This claim covers the present
example under discussion.

II. I have said many times that the source can adjust
its output to compensate for the destructive interference
and constructive interference in the system. It is ONLY
under zero interference conditions that all of the
reflected energy is dissipated in the source resistor.
You have failed to offer an example where that assertion
is not true GIVEN THE ZERO INTERFERENCE PRECONDITION.

The example under discussion is not covered by any of
my Part 1 claims.

Under the laws of physics governing transmission lines
inserting an ideal 1WL line does not change the steady-
state conditions. If you think it does, you have invented
some new laws of physics.

> You still have to explain where this destructive energy is stored
> for those 90 degrees. Please identify the element and its energy
> flow as a function of time.

Your request is beyond the scope of my Part 1 article.
If interference exists at the source resistor, the energy
associated with the interference flows to/from the source
and/or to/from the load. That condition is NOT covered in
my Part 1 article. Please stand by for Part 2 which will
explain destructive interference and Part 3 which will
explain constructive interference.

>> One advantage of moving the source voltage one wavelength
>> away from the source resistor is that it is impossible for
>> the source to respond instantaneously
>
> You have previously claimed that the steady-state conditions
> are the same (which I agree),

Glad you agree so there is nothing stopping you from an
analysis of the following example:

source---1WL 50 ohm---Rs---1WL 50 ohm---+j50
Pfor1--> Pfor2-->
<--Pref1 <--Pref2

Make Rs a 4-terminal network and a standard s-parameter
analysis is possible.

> but now you have moved to discussing
> transients, for which the behaviour is quite different.

Nope, you are confused. I am saying absolutely nothing about
transients. Why do you think an instantaneous power analysis
during steady-state is not possible?

> If you want to claim similarity, then you need to allow the
> circuit to settle to steady state after any change. Instantaneous
> response is not required if the analysis is only steady-state.

Are you saying that an analysis of instantaneous power
does not apply during steady-state? If that is true,
then all of your earlier analysis involving transmission
lines is bogus.

Taking these numbers and adding the Psource.50[91] = -2.468143 * -0.024681 = 0.060917 W found previously above,
we have Total = 0.060917 + 3.429023 + 96.510050 = 99.99999. Very close to 100w, but I am not sure of exactly what I am adding here.

I think you are right, that we should always be able to add the power on the line to 100w if we truely account for the power at any instant. This results from the trig identity that sin(x) + cos(x) = 1. Sin(x+90)= cos(x) so sin(x)+sin(x+90)= 1. This explains why the sum of the forward power and reflected power should always equal 100w.

Pg(t) is the result of a standing wave, containing power from Pf(x) and Pr(x+90). Only the power from Pr(x+90) is available to at a later time Prs(t+90+delta). Power from Pf(x+delta) is found in the transmission line.

The overriding issue is to account for all the power, which we are having a hard time doing. The current is flowing the wrong way for the source voltage at Ps(91) so the source is absorbing power. That negates the idea that the source has an impedance of zero when we also assign the source a voltage.

> > Of course the result is a another reflection. Is this the idea you were trying to communicate Cecil?

> to account for this power.

Does it help to notice that we are applying the power through two wires/paths. We then divide the power in half and say that the power to the resistor from the close half flows seamlessly from source to resistor. On the other hand, the second half of the source power flows through the transmission line and we say that it may never get to the resistor.

Something is wrong with this logic.

If we can't account for the power, it is because we are doing the accounting incorrectly.

I am convinced that accounting for the power can be done on an instant basis, but neither of us has done it on a mutually acceptable basis yet. Maybe if we pursue the trig identity sin(x) + sin(x+90) = 1, we can have a constant reference and avoid mixing forward and reflected powers?

Consider that what you are seeing is the flip side of the interference at the source resistor. When a local source is present, it can certainly absorb destructive interference energy and supply constructive interference energy. The following example has identical steady-state conditions but brings Pfor1 and Pref1 into play for the instantaneous values. I suspect that Pref1 is being completely ignored in the present analysis.

Vs(t)---1WL 50 ohm---Rs---1WL 50 ohm---+j50
Pfor1--> Pfor2-->
<--Pref1 <--Pref2

> If we can't account for the power, it is because we are doing the accounting incorrectly.

Try the above example and maybe it will become clear.

Pref1 = Pfor1(rho1^2) + Pref2(1-rho2^2) + interference1

Pfor2 = Pfor1(1-rho1^2) + Pref2(rho2^2) + interference2

The source power doesn't appear directly in the equations and need not be considered at all.

Pfor1 + Pref2 + P.Rs = Pfor2 + Pref1 (all average)

I suspect the above equation will account for all the energy components even at the instantaneous level such that:

Pfor1(t) + Pref2(t) + P.Rs(t) = Pfor2(t) + Pref1(t)

Please note that all of these power components exist when the two transmission lines are removed so this analysis is probably the key to understanding what is wrong with the earlier analysis.

Enlightenment will surely come if Art connects that antenna to the KW amp he
claims to have.

Go back to Art discription of his antenna.IT sounds to me as if it evolved
from a double bazooka.

Make a bazooka antenna with these mods:
.
Forget about the ladder line part of the dipole and make it all like the
center coax section.

Replace the coax section with lamp cord

Now make it fit in a couple of shoe boxes by coiling it all up.

Isnt this a good discription of Art's antenna?

Jimmie

The local 2m beacon (about 80 miles north and shielded by a local hill
) here is horizontally polarised. However if I beam south it is much
stronger on vertical polarisation. I have no idea why.

I think this would be right on the average basis. Because any sine waves of identical frequency can ultimately be added to make one wave, we can describe a single sine wave on the source side and another wave on the load/reflection side. There is no need for constructive or destructive interference as part of the final sine wave description.

On the other hand, if we want to understand how the final wave is assembled for each side of the resistor, we need the idea of constructive and destructive interference. Your pictorial showed only the single reflection, but as you have explained previously, there are many more reflections between the resistor and +j50 points until the power on the +j50 side finally stabalizes to some power level.

It seems to me like my spreadsheet found at

http://www.fairpoint.net/~rsparks/Smooth%20Power%20Reflection.pdf

captures a description of the forward and reflected waves as a single equation for each side of the resistor. The forward wave is y*sin(t) and reflected wave is y*sin(t+90).

If we want to learn how to find out how the source load begins at 100 ohms resistive and changes to 70.7 ohms reactive, we can either notice how the peak current has shifted from resistive to reactive (45 degree) from the combined waves described on my spreadsheet, or we can add all the reflections on each side of the resistor and come to the combined wave after many additions of ever smaller reflections.

>
> Pfor2 = Pfor1(1-rho1^2) + Pref2(rho2^2) + interference2
>
Interference1 and interference2 would be the combined effects of successive ever smaller reflections. Frankly, I don't see that combining the smaller reflections in this way to be of much value. It is like saying that the first reflection is special and the subsequent reflections equally special so we will give subsequent refections a group name, "interference". To me, all the reflections are "interference" and must be either added or subtracted in the same manner.

Nor do I, really. It could be that a close-by
piece of metal is oriented just-so to act as a
passive re-radiator for both horizontally and
vertically polarised waves (ie: it's at a
45-degree angle to both). It could be that your
beam actually has a relatively large, horizontally
polarised response in its back lobe. Or that
there is some interaction between the beam and its
(randomly polarised) feedline. Or that you live
in an anomalous neighborhood. ;-) ;-) ;-)

The sweepingly general statement I made about
radio waves not changing their polarity with
distance was made with the unstated assumption of
a propagation path relatively free of scattering
objects (re-radiators) and having a direct
line-of-sight path between transmitting and
receiving antennas.

We are analyzing a resistor isolated from the source and load
by 1WL of ideal feedline on each side. All we need are the
steady-state values of Pfor1, Pref1, Pfor2, and Pref2. It's
much like an s-parameter analysis of a 4-terminal box with
a 50 ohm series resistor. If we know a1 (Vfor1) and a2 (Vref2),
that is all that needs to be known to complete the analysis.
We don't actually need to know anything about the source and
the load if a1 and a2 are given.

> I think this equation is missing some terms, reflections 2,3,4...n.

The equation already contains all of those "missing'
terms because it is steady-state and all of those
terms have already been added in to the total.

From your previous posting, you gave the equation

Pfor1 + Pref2 + P.Rs = Pfor2 + Pref1 (all average)

Where Pfor1 and Pref2 were toward the resistor, and Pfor2 and Pref1 were away from the resistor. This equation seems to assume that the power to the resistor is zero. This is because the same current must flow in Pfor1 and Pfor2, and the same current in Pref2 and Pref1. The voltage drop through the resistor only happens when the circuit is complete on both sides of the resistor.

If we try to separate them as you are suggesting, we would have to recognize that it is also correct to say that

Pfor1 + Pref2 = Pfor2 + Pref1 + P.Rs (all average)

This is true because power only flows when the circuit is complete, and we can not say all the power comes from the left, or from the right. The power only flows when both are connected so the power must come from both sides.

There will never be one answer for your equation, unless, as you suggest, a1 and a2 are given.

Sorry for the obvious typo. The sign of P.Rs should
have been minus.

> This equation seems to assume that the power to the resistor is zero.

No, these are really basic concepts. The energy flow away
from a junction is equal to the energy flow into the
junction minus the dissipation in the junction.

(Pfor1 + Pref2) is the energy flow into the junction

P.Rs is the dissipation in Rs

(Pfor2 + Pref1) is the energy flow away from the junction.

(Pfor1 + Pref2) - P.Rs = (Pfor2 + Pref1) or

(Pfor1 + Pref2) = (Pfor2 + Pref1) + P.Rs

> There will never be one answer for your equation, unless, as you suggest, a1 and a2 are
given.

a1 and a2 *are* given - at least indirectly so they can be
calculated. Since we know Vs, Rs, and ZL, and given the two
1WL feedlines, we can easily calculate a1 and a2.

Finally got the batteries charged, discharged and charged again. I have
managed to fully charge them now.

How long should they last for with the MFJ-259 left on continuously being
used?

Is it normal to only get 10 - 15 minutes worth of on time before getting the
low battery warning on the MFJ?

Also the MFJ-259 is new. What is the best ways to check it to make sure its
working properly?

Thanks

That could well be the case. I just got a new cell phone
that had batteries that had no charge whatsoever.
At first the phone would not recognize them and start
charging. I'd check the voltage and zero.
I tried manually charging a small bit with a couple
of wires from a power source to see if I could kick start
em.
I'm not sure if that did the trick, but the phone finally
noticed the batteries and started charging.
There was nothing wrong with them, as when fully
charged, they last as long or longer than any of
my others.

The MFJ 269 manual says that it draws a maximum of 150 mA on HF and
VHF, and max 250 mA on UHF. Given the similarity of the instruments
I'd guess that the 259's current drain is similar to that of the 269
on HF/VHF.

This would suggest a useful run-time of around 12 hours for
fully-charged 2000 mAh cells, and perhaps 16 hours for the
larger-capacity 2500 mAh types. You'll get more time if the MFJ goes
into power-saving mode.

>Is it normal to only get 10 - 15 minutes worth of on time before getting the
>low battery warning on the MFJ?

If you're getting a flashing low-battery warning after only 10-15
minutes of use with freshly-charged cells - no, that's not good. It
would suggest to me that either one (or more) of the cells in the
battery stack is defective (or not fully charged) or that the MFJ's
low-battery detector is misadjusted.

Don't mistake the flashing low-battery warning, with the "display goes
mostly blank" sleep mode. The latter would be expected after some
minutes of non-use, while the former should not appear for hours.

NiCd and NiMH cells have a rather flat discharge characteristic - the
voltage remains almost the same across a broad part of the discharge
curve (from 90% charged to 10% charged). By the time that the voltage
starts to drop off, there's very little charge left in the cell, and
you have little warning.

Well-designed devices which were designed to run on NiCd batteries
will often have a low-voltage shutoff circuit, which deliberately
turns off the device once the voltage hits the "almost drained" knee
point of the curve (nominally 1.0 volts per cell or so). This is done
to avoid "over-discharging" some cells in the battery (continuing to
pull current through them after they're completely exhausted, but
while other cells in the battery still have some charge left).
Overdischarging can permanently damage a NiCd or NiMH cell.

I suggest that you try this: fully charge the cells. Put 'em in the MFJ. Turn it on. Let it run until the low-battery warning appears. Then, with the MFJ still turned on, use a digital voltmeter to carefully measure the voltage appearing across each of the cells in the battery, and across the full battery stack.

Under these conditions (fresh charge, little discharging, and a low current drain) the stack ought to be reading at least 12 volts, and probably more than that.

If you find a "freshly-charged" cell that is not reading at least 1.2 volts under these conditions, it's probably bad.

>Also the MFJ-259 is new. What is the best ways to check it to make sure its
>working properly?

Test a variety of known-value loads (e.g. 25, 50, and 100-ohm resistors) and confirm that the MFJ's readings are not unreasonably wrong.

Cut a length of coax of a known type, short the far end, perform the "velocity of propagation" tests shown in the manual. Typically a coax with a solid polyethylene dielectric will have a VOP of around 0.66, while a foamed-poly dielectric cable will calculate out at around 0.8 or so.

3978. Efficiency of 200-ohm hairpin matching

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-06 21:43:51 UTC
From: Antonio Vernucci <vernucci@tin.it>
Message-ID: <47f9440d$0$36449$4fafbaef@reader5.news.tin.it>
Source record: 26450

I have recently mounted a 6-meter long Yagi. The driven element is a (non-folded) dipole whose impedance is brought up to 200 ohm by significantly shortening it (so introducing a high series capacitive reactance) and using a (rather small) hairpin to resonate the residual reactance. The system is fed by a 4-to-1 balun (200-to-50 ohm) made of a half-wavelength cable. The SWR at resonance is almost perfect, but the SWR response vs. frequency is very sharp, this meaning that the system has a high Q. I am wondering whether such a 200-ohm feed technique could cause non negligible losses caused by the higher current circulating in the hairpin (due to its low reactance as well as to the high voltage on the high-impedance feed point, that is 200 ohm + reactance of the shortened driven element). 73 Tony I0JX

Hello Antonio,

When I understand you correctly, the series component of the dipole input impedance is 200 Ohm? I would expect value lower then 70 Ohms.

When 200 Ohms real component of Zi, you used a series hairpin to cancel the capacitive component. You can guess the loss by calculating the AC resistance of the pin.

Assuming homogeneous current distribution around the circumference, you can calculate the AC resistance with (assuming length of hairpin < 0.15 lambda):

Rac = 80*10^-9*sqrt(f)*le/d , Rac in Ohm, f in Hz, le (wire length) in m, d (diameter of wire) in m, valid for copper. For other materials (non magnetic), when conductance is factor 4 less (so 4 times higher spec. resistance), Rac doubles.

When the result for your hairpin << 200 Ohm, the loss is negligible.

In case of a parallel pin, you can use same technique, but in that case you have to calculate the inductance of the pin. With the inductance you know the reactance and the current that runs through it (for example with 100Vrms across it). With Rac you can calculate the power loss.

Hope this helps a bit.

the series component is probably just 25 ohm or so (due to the effect of the parasitic elements), but it is brought up to 200 ohm by shortening the dipole length and putting an hairpin in parallel (very well known technique to increase impedance). As a matter fact it matches very well with a 4-to-1 balun

> When 200 Ohms real component of Zi, you used a series hairpin to

No, the hairpin is in parallel to the dipole

Having all data available, it is clearly possible to calculate losses using the Ohm law. Mine was a question of more general nature. Does anyone have direct experience on whether the extra loss of a 200-ohm hairpin match (with respect to the more conventional 50-ohm hairpin match) is in pratice noticeable?

Thanks & 73

I wonder what you consider narrow bandwidth. 500 KHz seems to be about par
for a decent 6 m beam.

For what it'sworth, I looked at an MFJ-269 manual, and it claims to trickle charge at 10 - 20 ma. At that rate it will take a long time to charge a 2600 maH battery. They say minimum Vbat is 11V, but mine gets flakey below 12. You might want to measure the under load battery voltage when it fails and when you think it is fully charged.

I don't think a 2600 mAh cell will ever become anywhere near fully charged at that charge rate. That's barely enough to maintain an existing charge.

It is not really my problem. It is only a problem for
those who expect the imputed power of a partial contributor
to superposition to represent a real energy flow.

> If your steady-state equations
> for the new example are not identical to the steady-

> is obviously wrong with your previous analysis since
> it requires reflected waves to contain something other
> than ExH joules/sec, a violation of the laws of EM
> wave physics.

Not at all a violation. Just as one does not expect the
partial values of volts and currents during superposition
to produce a power value that represents a real energy
flow, one should not expect it from Es and Hs which are
the partial values being superposed.

You did say: "One advantage of moving the source voltage one
wavelength away from the source resistor is that it is impossible
for the source to respond instantaneously."

The words "respond instantaneously" suggested transient, rather
than waiting for the system to settle.

> Why do you think an instantaneous power analysis
> during steady-state is not possible?

Haven't said that. In fact, I think that is what I have been
doing.

> Taking these numbers and adding the Psource.50[91] = -2.468143 * -0.024681 = 0.060917 W found previously above,
> we have Total = 0.060917 + 3.429023 + 96.510050 = 99.99999. Very close to 100w, but I am not sure of exactly what I am adding here.

Using my notation where Ptot = Pfor + Pref we have
Pg(t) = Pf.g(t) + Pr.g(t)
= 50 + 50 cos(2wt) + (-50 + 50 cow(2wt))
= 100 cos(2wt)
If you subtract Pr.g from Pf.g(t) you get 100. If you follow through
the math, you will
find that this is what you have done.
Ps.50[91] + (- Ps.0[91]) + Prs[91]
which is
2 * Pf.g[91] + (-Prs[91] - Pg[91]) + Prs[91]
which is
Pf.g[91] + Pf.g[91] - prs[91] - Pf.g[91] - Pr.g[91] + Prs[91]
which is
Pf.g[91] - Pr.g[91]

which is
100

> I think you are right, that we should always be able to add the power on the line to 100w if we truely account for the power at any instant. This results from the trig identity that sin(x) + cos(x) = 1. Sin(x+90)= cos(x) so sin(x)+sin(x+90)= 1. This explains why the sum of the forward power and reflected power should always equal 100w.

If I recall correctly, it is sin**2 + cos**2 = 1.

> Pg(t) is the result of a standing wave, containing power from Pf(x) and Pr(x+90).

This is one way of thinking of it, but it is less misleading to
consider
that Pg(t) describes the actual energy flow, just as Vg(t) describes
the
actual voltage and Ig(t) describes the actual current. Using
superposition
Vf, If, Vr and Ir can be derived and from these Pf and Pr.

> Only the power from Pr(x+90) is available to at a later time Prs(t+90+delta). Power from Pf(x+delta) is found in the transmission line.

That negates the idea that the source has an impedance of zero when we also assign the source a voltage.

When a current flows out of a voltage source, the source is providing
energy. When
the current flows into it, the voltage source is absorbing energy. A
charging
battery is reasonable real world example.

We then divide the power in half and say that the power to the resistor from the close half flows seamlessly from source to resistor. On the other hand, the second half of the source power flows through the transmission line and we say that it may never get to the resistor.
> Something is wrong with this logic.
>
> If we can't account for the power, it is because we are doing the accounting incorrectly.

And the error in the accounting may be the expectation that the
particular set of powers chosen should balance. Attempting to
account for Pr fails when Pr is the imputed power from a partial
voltage and current because such computations do not yield powers
which exist.

Except that it is sin squared + cos squared that equals one.

When the two transmission lines are removed, how can these imputed powers exist? What impedance did you assign to the non-existant section of line to permit you to compute these powers?

Changes followed by "|".

The rec.radio.info newsgroup, first established in 1993, has been
recently revived by an active moderation team. We are currently seeking
suitable information, FAQ, and bulletin articles from the entire
rec.radio.* newsgroup hierarchy for simultaneous cross-posting to our
newsgroup.

We are seeking a replacement maintainer for the following information
bulletin formerly posted to rec.radio.amateur.* (and currently archived
at http://www.faqs.org/faqs/radio/personal-intro/ ):

radio/personal-intro
Subject: Guide to the rec.radio Newsgroups
Maintainer: jeffreyh@Hawaii.Edu (Jeffrey Herman)
Last Posted: 9 Nov 2001 06:18:17 GMT
Posting-Frequency: 15th of each month

We are willing to provide any technical support necessary to get this
article updated and automatically posted again at a regular interval.
This would include establishing contact with the original maintainer for
any necessary permissions. We would prefer to seek a new, dedicated
maintainer at this time, rather than start auto-posting the original
article ourselves.

Hello Tony,

Given your data and some assumptions about hairpin construction and
use, loss is negligible.

Given two coherent EM waves, W1 and W2, we know
that the power in W1 is E1xH1 and the power
in W2 is E2xH2. That is simple physics.

No matter what the results of superposition
of those two waves, the total energy in both
waves must be conserved. That is simple physics.

If you would think about what happens to two
coherent light waves in free space, you wouldn't
be able to justify your assertion above.

I have very deliberately chosen and limited the
scope of the examples to a 50 ohm environment.
Those imputed powers are therefore whatever an
ideal 50 ohm directional wattmeter indicates.

The distributed network model also works for circuits
as it is a superset of the lumped circuit model.

I did not expect you would be happy with the answer.

As long as you stick with simple assertions, followed
by sentences such as, "That is simple physics.",
spoken in a tone which says no further understanding
is necessary, you will be locked in the fruitless
search for the imputed reflected energy flow.

You seem to be saying that the answers would be
completely different if you chose a different
impedance for the non-existant transmission line.

Or even for the one wavelength line.

That does not make a very robust explanation.

If you ever comprehend that those RF waves in a
transmission line could just as easily be light
waves in free space, you will realize that your
"answer" violates the existing laws of physics,
i.e. EM waves whose energy content varies
according to your whim.

> for a decent 6 m beam.
>

This antenna shows an SWR of 1.7 at 150 kHz below the resonant frequency, where the SWR is just 1, so I consider it narrow. Another antenna I have, also using an hairpin match but at 50 ohm instead of 200 ohm, is by far broader. On both antennas I have about 100 feet of low-loss 1/4" Andrew hardline, so the SWR is only slightly influenced by cable loss.

Talking with the manfacturer, he told me that he preferred rasing the antenna impedance up to 200 ohm, instead than to 50 ohm, because a 4:1 cable balun can me more easily realized than a 1:1 balun. But doing so the feed system Q factor increases quite a lot, causing a significant bandwidth reduction. Moreover ohmic losses increase, due to the higher circulating currents (for a given RF power), but I am not able to predict whether such extra losses are significant or can be disregarded for all practical purposes.

More specifically, the December 1947 issue

From a practical standpoint, this paper is quite useful, although it mixes effects of the matching network in with the antenna, which the more rigorous analyses don't. It also doesn't provide any backup for its assertion of the validity of the "radiansphere" or "radianlength", hence the equations might not be valid over all possible antennas.

Wheeler's 1975 paper ("Small Antennas", IEEE Trans Ant & Prop, V AP-23, #4, July 1975, pp462-469) revisits some of the stuff in the earlier paper and provides more backup and describes the limitations of the "radian sphere" model (which he defines as the volume within which the reactive power density is higher than the radiation power density).

Of particular interest to would-be miracle small antenna builders is that he specifically mentions the problems if there is anything conductive or magnetic within the empty space oustide the "antenna" but within the radiansphere (defined as lambda/2pi). The latter paper also discusses some electrically small antennas (for 15 kHz, lambda=20km)

20 dB is probably representative of the "polarization purity" of a run
of the mill antenna in its preferred direction.

To be more specific is Wheeler refering to small FULL wave
antennas or smal fractional wave antennas.?
These are very different and one must be absolutely clear with
what Wheeler is dealing with.
My guess is that he is refering to fractional wave antennas
which is very common in the communication field

The current folowing through the source would be found from Ig which is 1.389317a in todays version of the spreadsheet (it was 1.439a previously). The power flowing INTO the source is 2.468143* 1.389317 = 3.429032w. This is the power Ps found in Column 11.

OK.

> > I think you are right, that we should always be able to add the power on the line to 100w if we truely account for the power at any instant. This results from the trig identity that sin(x) + cos(x) = 1. Sin(x+90)= cos(x) so sin(x)+sin(x+90)= 1. This explains why the sum of the forward power and reflected power should always equal 100w.

Your argument is correct to the extent that the power you describe is passing point Pg(t) at the instant (t). It is the equivalent statement that an observer watching cars pass on the freeway would make, saying "one blue car moving left and one red car moving right, so two cars are passing". Not wrong, just "how is the information useful"?

We then divide the power in half and say that the power to the resistor from the close half flows seamlessly from source to resistor. On the other hand, the second half of the source power flows through the transmission line and we say that it may never get to the resistor.

Something is wrong with this logic.

>
If we remove the transmission line from the circuit, we have an open circuit with no current. Without current, there can be no power. How can power arrive at Rs if there is no power coming through the transmission line?

Would it help to consider that before the "reflection from the short" arrives, power arrives via the transmission line path but the impedance is 100 ohms for our example, composed of Rs = 50 ohms and transmission line = 50 ohms? After the "reflection from the short" arrives, the impedance drops to 70.7 ohms so the power to the circuit goes up (assuming a constant voltage source). How can this happen if power is not carried via the "reflection from the short"?

You are right, the trig identity "sin(x) + sin(x+90) = 1" does not exist. Not a good idea.

hi Arthru,

But even more meaningful, are you speaking of large FRACTIONAL wave
antennas, or small WAVE full antennas? My guess is probably both
which is common in your communication.

> To be more specific is Wheeler refering to small FULL wave
> antennas or smal fractional wave antennas.?

Any size antennas... Wheeler's analysis essentially points out that when talking about "size" of an antenna, it's not just the mechanical dimensions of the metal that counts. You also have to account for stored energy in the fields around the antenna.

here's the abstract from the 1947 paper:
"A capacitor of inductor operating as a small antenna is theoretcially capable of intercepting a certain amount of power, independent of its size, on the assumption of tuning without circuit loss. The practical

efficiency relative to this ideal is limited by the "radiation power factor" of the antenna as compared with the power factor and bandwidth of the antenna tuning. The radiation power factor of either kind of antenna is somewhat greater than
1/(6*pi)* A*b/L^2
in which Ab is the cylindrical volume occupied by the antenna, and L is the radianlength (defined as 1/(2*pi) wavelength) at the operating frequency. The efficiency is further limited by the closeness of coupling of the antenna with its tuner. Other simple formulas are given for the more fundamental properties of small antnenas and their behavior in a simple circuit. Examples for 1-Mc. operation in typical circuits indicate a loss of aboute 35 db for the I.R.E. standard capacitive antenna, 43 db for a large loop occupying a volume of 1 meter square by 0.5 meter axial length, and 64 db for a loop of 1/5 these dimensions.
"
(forgive the typos when I copied it)

I would suggest that nobody attempt to argue the applicability or not of this paper from just the abstract. Get the paper, and the one from 1975 (and the ones by the other authors he cites: Chu, Fano, Wait, etc.). The maturity of the analysis of this sort of problem has advanced significantly over the last 60 years.

Wheeler is known for his work on small electricaly or fractional
wavelength antennas.
I was enquiring if the referred paper on limits were of small
electrical or fractional
wavelength antennas or has he broardened out to include small full
wave antennas.
Big difference

The big difference I refer to is that a fractional wavelength antenna
has limits on the
"Q" factor where a full wave antenna does not have any limits on ":Q"
since bandwidth is unlimited.
Obviously Chu,Wheeler and others are refering to fractional wavelength
antennas.
where my interest is small full wave antennas.
Frankly I feel that Chu and others are in error by pursuing the
integration of a small electrical
wave antenna in a closed arbitary border when Maxwells law,s requires
equilibrium within
the enclosed borders.

Wheeler worked with Woolsey and I believe they did seminal research on
the risible nature of fractional small wave large antennas when put
into a Skinner box to test stress levels. Fractional small wave large
antennas have the characteristic of being wide banded across a very
small percentage of frequencies with efficient operation in the low
teens to single digits on a length basis per unit charge.

You bring up the Skinner box. Are you not omitting the work of
Bedevere? Intercontinental speciation (viz African vs European) could
have an effect that should be considered.

I don't think it is the balun. I measured a 4:1, 1/2 wave 6m balun made of
LMR240 and got a 2:1 SWR bandwidth from 40 to 60 MHz. This was with an
MFJ-269 and about a foot of 50 Ohm coax. Load was a 1/2 W 180 Ohm resistor
(measured high).

>
> Tony I0JX

I'm trying to find a good way to wrap my mind around this "general"
problem. I'm not at a point I'm really comfortable with yet, but I
offer the following ideas as "food for thought."

First, the matching is being done essentially with an "L" network (or
rather the balanced version of an "L" network), where there is a load
resistance (the resistive part of the feedpoint impedance, which
includes radiation resistance and element loss resistance reflected to
the feedpoint), the series capacitive reactance of the feedpoing
element, and a shunt inductive reactance, provided by the hairpin.

Because shortening the driven element causes a decrease in resistance
and an increase in capacitive reactance, it's possible to find a
length that allows matching to any of a wide range of resistances.
But the higher the resistance to which you match, the shorter you need
to make the element and the lower the feedpoint resistance. The ratio
of feedpoint resistance to matched resistance determines the loaded Q
of the matching network; as you make the matched resistance higher,
the loaded Q goes up rather quickly. If you know the loaded Q and the
unloaded Q of the hairpin, you have a good handle on the amount lost
to heat in the hairpin: if the hairpin Q is two times the loaded Q,
half the power is dissipated in the hairpin, for example.

However, unless you build an antenna with a very low feedpoint resistance at resonance, there almost certainly won't be an efficiency problem: the reactance changes quickly enough with changes in driven element length that the resistance won't drop much by the time you reach enough reactance to get a match to 200 ohms. It appears that the loaded Q of the match to 200 ohms for your case will be less than 4. I would think unless you really messed up badly, the hairpin unloaded Q should be well in excess of 100, and if that's the case, the power lost in the hairpin would correspond to well under 0.1dB signal level change.

On the other hand, I'm surprised by the comment from the manufacturer about difficulties making a 1:1 balun. I have had good luck using ferrites and/or self-resonant coils of feedline and/or coils of feedline specifically resonated with additional capacitance. A 4:1 balun from a "hairpin" of 1/2 wave of coax, arranged symmetrically, is easy enough to make, but I would not rule out using a 1:1, if it has advantages for you.

Cheers,
Tom

Wow,

Cannot believe Wheeler has such a following, what he was dealing with at the time was low frequency loop antennas for navigation (e.g. LORAN, aircraft Omni stations) down around 300 to 500 KHz. If I remember correctly he made a statement in his paper that antenna was less than 1/6 of a wavelength in length.

I was interested because my design requirements for our customer was for a fairly wide bandwidth but with a shorten radiator rod to be canceled in a ordinary looking plastic housing for aesthetic reasons.

You are right, it is not a balun problem. It is a problem due to the reasons I
had explained in my post, which had nothing to do with the balun.

All OK. I however reckon that, due to the parasitic elements effect, the
radiation resistance of the driven element (before shortening it) would be in
the order of 20 ohm. So, impedance gets brought up by a factor of 10 or so.

His argument is that, for high-power operation (say 1500W), it is more
convenient for him to provide a quarter-wavelength 4:1 balun made of RG-142

teflon cable than a sealed box with a 1:1 coil on an ironpowder toroidal core. I mentioned him that, just using some extra length of RG-142 cable, he can easily build a 1:1 balun, and hence design the antenna matching system for 50 ohm instead of 200 ohm.

I hope he will listen to me, because that antenna is really narrowband!

Also, I think the 4:1 , 1/2 wave would be a voltage balun. I am considering adding a ferrite 1:1 on the feedline side of the the coax balun. There is some feedline radiation right now.

My vision is returning and could turn out to be
the best vision that I've ever had in my life. :-)

You have been asking for the mechanism for storage
and return of the interference energy in the system.
That mechanism is standing waves. Are you aware that
standing waves store energy and return it to the
system every 90 degrees? In the examples being discussed,
there are standing waves inside the source. For the 1/8WL
shorted line, there appears to be 125 watts of forward
power and 25 watts of reflected power at points on each
side of the source.

With powers given in average values, the circuit that
you should be using for your instantaneous power
equations is:

```
50 ohm
----50-ohm----/\/\/\/\----50-ohm----
125w--> 100w 50w-->
<--25w <--50w
```

I will be very surprised if the instantaneous
powers don't balance.

Your previous problem is that you were using net
power values on one side of Rs and component power
values on the other side of Rs. That's apples and
oranges, a known no-no.

Hello,

Imagine 10 Ohms radiation resistance + capacitive component after shortening the open dipole radiator. When you convert that to 200 Ohms via a parallel inductance (hairpin), the Q factor of such a network is about 4.4. At 50 MHz that will result in a bandwidth (VSWR=2) of 8 MHz.

A 200 Ohms to 50 Ohms coaxial balun will have a lower Q factor. So the combination of balun and L-network will certainly have a useful bandwidth >> 340 kHz.

Maybe the radiation resistance is less (you can derive that from the hairpin inductance) and/or the antenna is by nature (very) narrow band.

Best regards,

I regret that I haven't been able to take the time to contribute to or even follow this very interesting thread. So please pardon me if the following comment isn't relevant.

The quoted statement reminded me of an earlier thread where Keith asked a similar question, and proposed some interesting alternative explanations. The point in question was a current node in a lossless line which had infinite SWR, e.g., an open circuited line. A look at the energy flow in the vicinity of the node reveals a plausible explanation. It turns out that energy is being stored at the node, in the line's capacitance, to the tune of C*V^2/2. For half the cycle, energy is flowing into the node equally from both directions, so the power measured at that node is zero. During the other half of the cycle, energy is flowing out of the node equally in both directions. So the power remains zero at the node for the entire cycle. This is, of course, consistent with the zero current at the node. The node's energy increases to a maximum and down to zero periodically in step with the square of the node voltage.

Now, I don't know of any way to assign "ownership" to bundles of energy. But let's suppose that the energy which flows into the node from the left side during the "inhalation" part of the cycle is the energy which flows out to the right during the "exhalation" part of the cycle, and the energy flowing into the node from the right exits on the left. So now we've managed to get energy past the node going in both directions while maintaining zero power and current at the node and conserving energy as we must.

This can be seen graphically with the little TLVis1 program I made up a while back -- see the thread of that name for more info. The phenomenon I'm describing can be seen in demo 4, one cycle from the output (right) end of the line.

>Can they (Eneloops) be charged in a conventional NiMH charger, or do
>they require a proprietary charger?

Sanyo's own words:

"Basically eneloop is a modern Ni-MH battery, which can be charged
like any other Ni-MH battery.

Therefore eneloop can be charged also with other, modern chargers,
which are suitable to charge Ni-MH batteries.

However, SANYO cannot accept any liability for the function or safety
of chargers made by other manufacturers.

Also SANYO cannot be held responsible for any damage to eneloop
batteries caused by unsuitable chargers."

On a different Sanyo page (http://www.eneloopusa.com/eneloop.html) they
say that they only provide warranty on the batteries if an Eneloop
or other Sanyo-branded NiMH charger is used. "Quick" chargers (those
charging in under 2 hours) should not be used, as these may reduce the
life of the battery... "2 hours or more" charging rate is recommended
(e.g. 0.5C or so).

A lot of people seem to like the various Maha chargers. One of my
friends here uses a Maha MH-C9000, which is relatively expensive
(currently $60 from Thomas Distributing) but is *extremely* flexible
and adaptable... you can select the charging and discharging rate for
each battery, perform one or more break-in or discharge/recharge
exercise cycles, etc. I have one on order and plan to try it out with
my various NiMH cells.

Seems to me that almost any modern NiMH charger, with a charge rate of
around 500 - 1000 mA per cell, and an effective full-charge cutoff
circuit (thermal and delta-V) would work fine with Eneloops and
similar low-self-discharge NiMH cells.

USMCBrat-

I think the cubical quad may be the best antenna for your situation, but
there are other options.

"Rubber duckie" refers to the shortened rubber-coated antenna on a
walkie talkie. If several of these were arranged as a yagi, they would
not have the sharp points your full size yagi has.

Another is called a "Doppler Direction Finder", and requires an
electronics package. It has 4 vertical antennas arranged in a square on
a metal plate. Take a look at
<http://www.ramseyelectronics.com/cgi-bin/commerce.exe?preadd=action&key=
DDF1>
for an example of this kind of system. The vertical antennas might be
"rubber duckies" as well.

Art wrote:
"Where must the "curl" vector be placed in general to justify the right angle radiation statement that all your books apparently parrot?"

Look up divergence and curl for yourself as I have no special characters on my keyboard and I am a lousy typist too. You can find what you seek in the chapter on Maxwell`s equations in ITT`s handbook "Reference Data for Radio Engineers" This starts on page 43-1 in my 5th edition.

No contradiction to Kraus or Terman is to be found. The right or left hand rules are good. Magnetic lines of force encircle the current and electric lines are perpendicular to them as they begin and end on the wire in their radial attachments. Both fields are at right angles to each other and both are also at right angles to the current flow.

There is no abberation for diamagnetic materials. The fields are the same if the wire is lead instead of copper. Diamagnetic distortion is a myth. Velocity and loss are hardly different. You need to coat the conductor with a diecectric if you would get more wavelength in a given length of wire.

Best regards, Richard Harrison, KB5WZI

I would also have a search for 'Handifinder', it is a simplified version of the above that uses 2 small loop antennas and is easily hand portable. It is cheap and easy to build and I think kits are available. It does have a 180 degree ambiguity but in real use that is not a great problem.

That is very helpful, Dave, especially since I have a very fast charger
that would be very hard on these cells.

I'll get a set and use them on my slower chargers, and also warn people,
no faster than a two-hour charger for the new chemistry cells. (I have a
15 min Energizer charger that does well with Energizer AA and AAA cells,
but have not had a chance to evaluate lifetime. The cells charge nicely,
but 15 seems very hard charging.

Roy Lewallen wrote:
> Now, I don't know of any way to assign "ownership" to bundles of energy.

One way is to add a unique bit of modulation to each
bundle of wave energy. I am fond of using a TV signal
and observing ghosting on the screen. This, of course,
assumes that the modulation stays with the same component
wave to which it was originally associated.

> now we've managed to get energy past the node going in both directions
> while maintaining zero power and current at the node and conserving
> energy as we must.

This agrees with the distributed network model. Since
there is no impedance discontinuity and no impedor at
the node, there can be no reflections at the node. The
forward wave flows unimpeded through the node as does
the equal magnitude reflected wave. The net energy flow
is zero. The average energy flow is zero.

Anyone who believes there is zero energy at a standing-
wave current node should touch that point on a transmission
line (which just happens to be the same point as the
maximum voltage anti-node).

One must be careful not to confuse the net signal with the
component signals. One must be careful not to confuse the
average values with the instantaneous values.

This can best be visualized using light waves in free
space. Unimpeded EM waves do not bounce off of each other.

Source record: 26253

Having made small full wave antenna with a swr in Sino soidal form
ie reactance which is quite normal I decided to get back to basics
and
view it as a pendulum ala a tank circuit equivalent
lwhere lengthening the pendulum changes the peried.with consequent
damping
via incresing of "slow wave"
Doing this to the antenna structure provided an antenna that did not
exceed
a swr of 4 from 2 mhz upto a 100 Mhz.plus (very few deviations above
3:1)
What the dampening did was to smooth out the resistive and reactive
values
to produce a response very similar to a log periodic except, of
course. it was
a small full wave electric antenna with a omni directional response.
(it can be made directional)
Tried it also on the local TV stations (60 miles away) and it worked
extremely well
such that it looked like HDTV! Again this points out the requirement
for equilibrium
of antennas in tank circuit form. With care, an antenna can now be
made
with extremely flat response for ALL frequencies since the impedance
can be made near constant.By the way the antenna took 200 watts key
down for 1 min
without any hint of failure.(the impedance reference value was 50
ohms
and a MFJ 259B was used tho any datum impedance can be chosen)
Whether my theories are correct or not with respect to academia, to
have such antennas
in practice where responses can be measured it would behove hams to
replicate them
and allow the academics to follow up later. Will now modify some
rubber duckies
for the local police force to extend the distance range as our county
is quite large.
Regards
Art Unwin KB9MZ......XG (uk)

There you go again, trying to shove your words
into my mouth. (Pattooieee!) Please don't do that.

You have apparently done the math and found it
to be valid so, once again, you have to change
the specified conditions in order to try to make
your point.

A Z0 of 50 ohms is the *only* characteristic
impedance that will meet the specified precondition
of zero average interference. Choosing any other
characteristic impedance will move the example
outside of the scope of my Part 1 article. I
understand why you want to do such a thing but
obfuscation, diversions, and straw men are not
part of the scientific method. My Part 1 article
has a very narrow scope. Please abide by it.

Killing a snake and using it for the transmission
line would likewise violate the same specified
preconditions. Please feel free to do that and
report the results.

Yes, I had similar thoughts, but a bit different. First, I think it's safe to say that if, at resonance, the driven element presents about 20 ohms at the feedpoint, shortening the D.E. only a little will give enough capacitive reactance to allow the hairpin match to 200 ohms. Even if the D.E. looks like 5 ohms, the "L" network match still gives a 3dB bandwidth of 8MHz at a 50MHz center, or 3MHz 1.5:1 SWR bandwidth. I think we need to look somewhere else for the answer to the narrow bandwidth. My working hypothesis at the moment is that it's in the antenna, or perhaps rather in the combination of antenna and matching network. Note that the calc for the L match assumed a constant capacitance, but the antenna will not, in general, look

anything like a constant C even over a fairly narrow frequency range. I just ran EZNEC on a frequency-scaled version of the 14MHz 5 element Yagi included in the sample files, with the D.E. slightly shortened to allow a decent hairpin match to 200 ohms at the design center frequency. I did a frequency sweep, 49 to 51 MHz, in 0.25MHz steps. Over that range, the equivalent series capacitance changes from 59pF at the low end to 138pF at the high end, and at least by NEC2's prediction, the impedance changes especially quickly around 51MHz--both reactive and resistive parts. 50.75MHz: 10.3-j31.76; 51MHz: 3.91-j22.56, quite a large percentage change in 250kHz. Having the effective series capacitance change that quickly will cause the matching network to behave very differently than it would with a capacitance element that is fixed.

Is it possible to lengthen the D.E., causing it to present an inductive reactance at the feedpoint, and match that (to 200 ohms, or to 50 ohms) with a shunt capacitance? That may work better, giving a broader SWR bandwidth. The resistive component should be higher, further lowering the Q, and I suspect the reactance won't change so quickly with frequency. I don't have time at the moment to compare the two, but may this evening. It may also be possible to raise the resistive part to 50 ohms and match to 50 with a series capacitance.

Cheers,
Tom

Good, constructive suggestion, Tom. Kudos for putting in a bit
of design/analysis effort on this rather than just shooting from
the hip. This is definitely a weird way of driving a yagi. It makes
me yearn for the old TV-antenna schemes that used folded
dipoles for the driven element, suitably split-up between upper
and lower wires so as to give a 300-ohm terminal impedance even
with the resistance-lowering effects of the reflector and directors.

I'm not familiar with that analyzer but the websites indicate it uses AA cells--presumably rechargable ones have been supplied with your 259Z. One thing to check is that the cells are correctly inserted (sorry but it happens often!) and that they're not protected by little plastic covers on the positive terminals. Rechargable batteries that come with new equipment often have tiny bits of plastic that have to be removed by the end user. This isn't always mentioned in manuals.

If it's brand new and has never worked with the batteries alone, you might have a manufacturing defect--they're not unknown in MFJ gear, not that I'm knocking MFJ. You'd want to take a quick look at the charge/no-charge switch, the bypass (if there is one) on the connector for the PSU on the radio, etc.--simple things easily visible. You might also try charging the AA cells in a standard charger, and seeing if the 259Z then works properly with the batteries--if that doesn't work, it might be the cells you have and not the analyzer itself.

That is exactly the point! It would not be correct to calculate bandwidth on the basis of the Q factor at resonance and assuming that the capacitive antenna reactance is equivalent to that of a fixed capacitor.

Today I have discovered another shortcoming of that antenna. After raining cats and dogs, the antenna resonant frequency gets lowered by about 130 kHz due to the influence of the wet terrain. That is really a lot if you consider that, after making very accurate measurements with a Bird wattmeter, the antenna bandwidth is only 100 kHz at 1.4 SWR!

I am considering to re-build the driven element for 50-ohm match, by using a longer driven element and a 1:1 balun. However it will not be easy to find the optimum situation because there are two variables to be adjusted, that is the driven element length and the hairpin length.

Also, I am not too sure on to which extent using a longer driven element would influence the antenna radiation pattern.

Any comment?

Though the Q calculation doesn't give the right SWR bandwidth for the
antenna/matching system, it does tell you that (with such a low loaded
Q), it should not be difficult to make a hairpin or even standard
helical coil inductor that has low enough loss that you can ignore the
effect.

I believe that the physical length of the driven element in a Yagi is
much less important than the tuning and spacing of the parasitic
elements. The question becomes something like this: what is the
relative amplitude and phase of the current in each parasitic element,
for some excitation of the driven element? A Yagi is a system of

coupled resonators, like a system of coupled pendulums. If one of the pendulums is driven at a particular amplitude and frequency, even if it's not that pendulum's natural frequency, the rest of the pendulums will follow along pretty much the same as if the driven pendulum was tuned to have that natural frequency. In the antenna, the difference will only be in the coupling from the driven element to the others, and I believe that changes only slightly as the length of the driven element changes.

But I may be wrong about that, and await my re-education. ;-) But I just ran EZNec on the example "NBS" 3-element 50.1MHz Yagi, varying the nominal 110 inch long D.E. by +/- 10 inches, and saw the expected fairly large variation in impedance, but only 0.02dB change in gain over that whole range, with similarly small variation in F/B ratio and beam width. The longest D.E. I ran was also the highest gain (by that tiny amount), and provided enough inductive reactance that the feedpoint could be tuned to resonance and present 200 ohms by shunting with about 55pF capacitance. Next to try: compare the SWR bandwidths of the hairpin (inductive) shunt of a shortened D.E. and the capacitive shunt of a lengthened D.E.. Unless someone offers a better test case, I'll use the NBS 3 element Yagi...

Cheers,
Tom

Hi Tom,

the results you got on EZNEC are encouraging. Nevertheless I would not like to try using a lengthened element in conjunction with a capacitor, as the difference between that configuration and the original configuration would be the maximum (although it would be much easier to adjust a capacitor than the inductance of an hairpin).

What puzzles me is that the antenna manufacturer reported me having sold several hundreds of those antennas, and no one has reported him the bandwidth being too narrow or the exagerated wet terrain influence.

I am not sure on what I am going to do, also because I am not 100% sure on whether the bandwidth problem is only due to the matching system, or it is also

due to the particular antenna design.

My original intention was to compare this 50-MHz long Yagi antenna (32-foot boom) against a smaller antenna (11-foot boom) I have on another tower, so as to determine how much a bigger antenna really helps during multiple-hop sporadic openings to US and Japan.

Probably for the forecoming sporadic-E season (May-August) I will leave things as they are, and just try to assess the practical advantages of the bigger antenna. After that I will see what I shall do.

Thanks very much for the useful discussion.

> bandwidth.

Hello Tom,

Fully agree with you. I gave the values for a 20 to 200 Ohms match to show that the problem is not in the matching, but in the antenna. Even matching from 20 to 50 Ohms will not give sufficient bandwidth, because actual BW is far below the BW of the matching network (with 20 Ohms termination).

I think we need to look somewhere else for the answer to
> the narrow bandwidth. My working hypothesis at the moment is that

That rapid Im(Zant) change is the reason for the narrow BW.

Did you also scale the thickness of the elements?

I did a frequency sweep, 49 to 51 MHz, in 0.25MHz steps.

I did use length extension for very thick mesh dipoles for VHF air band. Their resonant impedance is less then 50 Ohms (because they become short). Some additional length gives some inductance to use a parallel capacitor match and (most important) bandwidth increase.

I don't know whether this will give sufficient BW improvement for the Yagi as the Q is also determined by the reflector en directors. I am looking forward to your simulation results.

Art wrote:
"But ham radio and the Navy have proved him (Terman) wrong with T2FD testing."

Art has likely tried a VHF or UHF antenna by rotation within a linearly polarized wavefront. If so, he has experienced cross-polarization and noted about 20 dB loss when cross-polarized in the field.

My WW-2 navy ship used a Marconi (inverted L) antenna for HF communications with a Collins TCS. A signal reflected by the ionosphere gains random polarization in the process. The vertically polarized Marconi does well with a ground wave over short distances even at HF over sea water. We had no slopers. The VHF and UHF antennas were all vertical whips to cover all azimuths. Art`s inclined antenna is in general a myth.

For rntertainment, we had a broadcast receiver called the RBO. It too used a Marconi antenna as all medium wave broadcasts are launched from vertical antennas. It worked well as would be expected of a broadcast receiver.

hi

Is there any good site that i can check with prior to moving to
investigate if a particular town/city is going to be tower
friendly

for example a job might open up for me in tampa, fl so i
wanted to check the good/bad places around there to see what is
good

typically i wanted to check:

a) tower friendly
b) no power over ethernet
c) strange but known rf stuff that might cause ham interference

any tips /links appreciated

Tony,

Some thoughts.

You are suggesting that it is easier to make a low loss capacitor that is located at the feedpoint in a hostile environment, than it is to make a low loss inductor (the hairpin).

Just as the hairpin is a s/c stub for inductive reactance, you could use an o/c stub... but remember that transmission line elements are a path to low Q reactors, use thick conductors for the transmision line (which for an o/c stub will need to be much longer than for the s/c stub).

>

Only hundreds?

Hy-Gain have used this feed system on 2m antennas for a very long time. Yes, their gain figures seem a bit generous, but the hairpin is a viable commercial option.
>

My gut feeling is that optimised long Yagis have narrow bandwidth because of the large number of elements with role that is frequency critical. A short Yagi has wider bandwidth with the same feed system.

It is a long time since I read your first post, but narrow bandwidth can be an advantage. It reduces out of band signal reach your first amplifier where it will mix and produce IMD products that may be in-band. Narrow band antennas help to provide the selectivity that is lacking in many /

most modern radios.

Owen

Yes, EZNEC lets you scale everything in the same proportion in one
quick operation.

>
> I did a frequency sweep, 49 to 51 MHz, in 0.25MHz steps.

> looking forward to your simulation results.

Yes, of course. If the antenna itself is not wide-band, there is
rather little you can do about it. It may be possible with a more-or-
less complicated network to make the SWR bandwidth somewhat greater
(assuming still low loss--if you have a lossy network, you can make
the SWR bandwidth very large -- ;-) But making the SWR bandwidth
large does not make the antenna's gain bandwidth large. That is, for
a given set of directors and reflectors, the pattern will change with
frequency without much regard for what you do to get power into the
antenna.

Thanks for the encouragement about running some simulations. I'll
report results as I have a chance, probably this evening (US Pacific
coast time).

Cheers,
Tom

Our cat has equal length mittens
and a symmetrical color scheme. :/
It's in equilibrium. Maybe I oughta fire
up the old rig, hook up some gator clips
to her legs, and see how she radiates from
2-100 mhz.. :+
I suspect if I place her on a steel patio table
as a ground plane/reflecting device, that would
increase the gain to the point that a government
grant surely would be inevitable. :)
They would probably make me cover boy
of QST for the next April edition.

Hello Tom,

I do not have experience with EZNEC, so I didn't know that it also scales element diameter.

Fully agree with regards to VSWR BW, gain BW and wide band dummy loads....

Here it is UTC+2, so it is time for me te visit my bed for some hours. Tommorow VAT administration is waiting.

Best regards,

Wim

Hi Wim and lurkers,

Yes, EZNEC has some nice features. I exercised a couple of them tonight, doing frequency sweeps with inductive and capacitive matching. I did cheat: since I do not know the dimensions of the hairpin match, I elected to just use a pure lumped inductance. I suppose the error compared with a transmission line stub (hairpin) won't be great. I also used for the first time ASCII file import for the wire description, making use of Excel to generate the wires. (Why did it take me so long?? ;-)

Somewhat to my surprise, I found that the SWR bandwidth of the shortened D.E. (driven element) loaded with a shunt inductance and that of the lengthened D.E. loaded with a shunt capacitance was not so different.

The antenna I picked to model was one in the Orr and Cowan book, "The Beam Antenna Book." It's a 6-element 1.20 wave long design, with 0.2 waves D.E. to reflector, and 0.25 waves D.E. to first director and also between each adjacent pair of directors. For 6 meters it is a little shorter than Tony's antenna, but not very much shorter. But the elements (per Orr and Cowan's numbers) are 2 inches (about 50mm) diameter. The large diameter almost certainly contributes to the fairly broad bandwidth. All models below are done in freespace.

For the shortened D.E.: D.E. length = 95.4 inches. Feedpoint impedance at 50.1MHz is 16.32-j54.63 ohms. Gain varies from 11.78dBi at 49.5MHz to 11.98dBi at 50.1 to 11.68 at 50.5. f/b varies uniformly from 19.43dB at 49.5 to 8.21dB at 50.5. Matched at 50.1MHz to 200 ohms with 189.4nH shunt at the feedpoint yields a 1.4:1 SWR bandwidth of about 49.89MHz to 50.28MHz.

For the lengthened D.E.: length = 115.8 inches; impedance at 50.1 = 29.28+j70.7 ohms. Gain: 11.81@49.5, 12.05max, 11.82@50.5. f/b shows same uniform degradation with increased freq; 20.92@49.5 to 8.52@50.5. 38.35pF shunt across feedpoint yields 1.4:1 SWR BW of about 49.89 to 50.34MHz, just slightly greater than the shortened one.

(Neither of these includes frequency effects of the 4:1 balun to get back to 50 ohms...)

I also tried a much-lengthened D.E., to get it up to 50+j204.1 ohms. Then a series 15.57pF gives a 50 ohm match. Gain is similar to above, 11.83dBi --> 12.11dBi --> 11.93dBi, and f/b is also similar, 22.82 --> 8.83. I notice both the gain and the f/b improve slightly as the D.E. is lengthened, though it's small enough that you'd never notice it--it would be swamped out by other effects. The 1.4:1 SWR BW for this configuration is about 49.85MHz to 50.32MHz; this of course against a 50 ohm reference which is different from the first two examples above which are against a 200 ohm reference.

OK--I think I got all the critical stuff in there...

Cheers,
Tom

It probably isn't.

However, you could get an idea from my Two Wire Line Loss Calculator
(http://www.vk1od.net/tl/twllc.htm). It looks like a hairpin made of 4mm
dia aluminium 50mm spacing and 150mm in length give an impedance of 0.02
+j61... so the Q is probably mainly determined by the end connections.

a o/c stub made of 4mm dia aluminium 50mm spacing and 1300mm in length
give an impedance of 0.07-j80... so, it is not quite as good
electrically, it is unweildly and end connection resistance will probably
still be significant. This is no doubt why people use a hairpin in
preference to an o/c stub!

Hello Tom,

Regarding the "cheating", no problem with that. When length of hairpin is far below 1/8 lambda, difference with lumped component is negligible (for this situation).

Owen mentioned that a 150mm hairpin has the required reactance. The 0.02 Ohms loss resistance in the hairpin does not dissipate significant power (not measurable in practice within the antenna setup). This also shows that Tony does not have to worry about hairpin loss, even in his 200 Ohm intermediate impedance.

Your simulation made fully clear that Tony's problem is in the antenna and not in the matching.

Thanks for sharing your results,

Wim

> > superposition
> > Vf, If, Vr and Ir can be derived and from these Pf and Pr.
>
> Your argument is correct to the extent that the power you describe is passing point Pg(t) at the instant (t). It is the equivalent statement that an observer watching cars pass on the freeway would make, saying "one blue car moving left and one red car moving right, so two cars are passing". Not wrong, just "how is the information useful"?

Pg(t) is the actual power at that point in the circuit. It can be
derived by simply multiplying the direct measurement of the actual
voltages and currents at that point in the circuit. One measures
the same voltages and currents regardless of whether it is a
transmission line to the right of point g, or the equivalent
lumped circuit element.

While Vf, Vr, etc. can be used to derive the same information and,
therefore is arguably just a different point of view, Vf and Vr,
If and Ir, etc., must always be used in pairs to arrive at the
actual circuit conditions. It is when one starts to look at them
separately, as if they individually represent some part of reality,
that confusion awaits.

Thus I strongly suggest that Vg, Ig, Pg, represent reality. The
others are a convenient alternative view for the purposes of
solving problems.

Typically we see Vg split into Vf and Vr, but why stop at two.
Why not 3, or 4? Analyzing a two wire telephone line will use
four or more, forward to the east, forward to the west, reflected
to east, reflected to the west, and sometimes many different
reflections. How do we choose how many? Depends on what is
convenient for solving the problem. The power of superposition.
But assigning too much reality to the individual contributors

can be misleading.

> > > If we can't account for the power, it is because we are doing the accounting incorrectly.

> > account for Pr fails when Pr is the imputed power from a partial
> > voltage and current because such computations do not yield powers
> > which exist.
>
> If we remove the transmission line from the circuit, we have an open circuit with no current. Without current, there can be no power. How can power arrive at Rs if there is no power coming through the transmission line?

There is power coming from the transmission line. Looking at Pg(t),
some of the time energy flows into the line, later in the cycle
it flows out. The energy transfer would be exactly the same if the
transmission line was replaced by a lumped circuit element. And
we don't need Pf and Pr for an inductor.

But this flow is quite different than the flow suggested by Pf and
Pr. These suggest a continuous flow in each direction. It is only
when they are summed that it becomes clear that flow is first in
one direction and then other.

> Would it help to consider that before the "reflection from the short" arrives, power arrives via the transmission line path but the impedance is 100 ohms for our example, composed of Rs = 50 ohms and transmission line = 50 ohms? After the "reflection from the short" arrives, the impedance drops to 70.7 ohms so the power to the circuit goes up (assuming a constant voltage source). How can this happen if power is not carried via the "reflection from the short"?

It goes up because the impedance presented by the transmission
changes when the reflection returns. This change in impedance
alters the circuit conditions and the power in the various
elements change. Depending on the details of the circuit,
these powers may go up, or they may go down when the reflection
arrives.

More correctly, the energy is stored in the distributed
capacitance and inductance of the transmission line.

> In the examples being discussed,
> there are standing waves inside the source.

There is no capacitance or inductance in the source to
store energy.

Perhaps. But I don't need more examples where the powers balance. I already have the one example where they don't. And it only takes one to disprove an hypothesis.

> Your previous problem is that you were using net
> power values on one side of Rs and component power

But there are no component powers in the source. It is a simple circuit element.

> assumes that the modulation stays with the same component
> wave to which it was originally associated.

But as soon as you modulate, you no longer have sinusoidal
steady state.

You can split the signal up into its spectral components
and, using superposition, analyze the circuit for each
spectral component individually, then sum them to obtain
the total system response. But chasing the energy with
one frequency is hard enough. The conundrums that arise
when doing it for several are much worse than the ones
here.

For your enjoyment consider the composite signal
cos(9.95*2*pi*t)+cos(10.05*2*pi*t)
working into 1 ohm.
The imputed average power for each of the components is
0.5 W. The total average power is 1 W as expected.

Consider the 1 second interval from 4.5 to 5.5 seconds.
In this second 0.016393 joules flow for an average
power of 0.016393 W. But the sum of the imputed power
in the two spectral components is 1 W. Where did the
missing energy go?

Just another example of why assigning too much reality
to the imputed powers of the components of superposition
is misleading.

In other examples, you have suggested inserting a zero length transmission line to aid analysis. Why not insert a zero length transmission line with an impedance to produce the desired reflection? At steady state the reflection cancels but this would be due to the redistribution of energy according to your explanations.

No one has said there is zero energy. Only that there is zero energy flow. For energy flow, one needs simultaneous voltage and current.

> One must be careful not to confuse the net signal with the
> component signals.

Agreed. Assigning too much reality to component signals is seriously misleading. Now actual voltages, currents and powers, that's a different thing.

> One must be careful not to confuse the
> average values with the instantaneous values.

Until one can grasp the simplicity of a transmission line, moving to the complexity of free space offers nothing but obfuscation.

Did you not say that 50 ohms for the non-existant
line was the correct impedance because other impedances
would yield the 'wrong' answer?

> You have apparently done the math and found it

Did you not say that adding 1 wave length of transmission
line does not alter the conditions? Are you now saying
it does?

> I

Yes. That is why I prefer the simplicity of Fig 1-1
without the non-existant transmission lines.

Richard
Over the years you have insulted my work as I have shared most of it
with my fellow hams.
I shared with all the details of my antenna work and in this thread I
have shared with all
how I utelised the connection between mechanical laws and electrical
laws of Maxwell Gauss
Newton and the proof with respect to radiation. This last thread
proves the existence of the universal
law where I used the mechanical laws of the pendulum and applied them
to the electrical laws
which produced the antenna. It is this proof that I have provided
which is the most important step
in my work.Considering that Einstein spent his whole life searching
for this and eventually turned
away from the classics to those of relativity makes me very proud of
my work.
I shared it with hams because of their love with respect to antennas
but that is a love of the past.
I am extremely disapointed that hams did not go on this jorney with me
or even supply encouragement.
However I am now at the end of my quest and thus will retreat from
this newsgroup where it appears
emotion has overtaken the the employment of skill to pursue the holy
grail that most have given up.
Regards to all as I depart where I will not be privey to your replies
and can thus concentrate on other matters.

Tom and Wim,

I agree with your concluion that the bandwidth narrowness is due to the antenna design and not to the matching system.

I have simulated the antenna on EZNEC and the narrow band property of the antenna is very evident.

I would like to also put the hairpin in the EZNEC model, but I am not very good at EZNEC and I would not now know to do it.

If you are interested I can send you the EZNEC file via e-mail.

Of course they represent *net* reality but we are trying
to determine what is happening at a component wave level.
Defining the component waves out of existence is an un-
acceptable substitute for ascertaining what is happening
in reality.

> Typically we see Vg split into Vf and Vr, but why stop at two.
> Why not 3, or 4?

Because two is what a directional wattmeter reads. The
two superposed waves, forward and reverse, can be
easily distinguished from one another. Two superposed
coherent forward waves cannot be distinguished from
each other. That's why we stop at two - because it is
foolish to go any farther.

> There is power coming from the transmission line. Looking at Pg(t),
> some of the time energy flows into the line, later in the cycle

OTOH, the distributed network model is a superset of
the lumped circuit model so the inadequate lumped
circuit model might confuse people. Hint: changing
models to make waves disappear from existence doesn't
make the waves disappear.

The lumped circuit model is adequate for lumped circuits.
It is inadequate for a lot of distributed network problems.
If the lumped circuit model worked for everything, we
wouldn't ever need the distributed network model.

I suggest that you take your circuit and apply distributed
network modeling techniques to it including reflection
coefficients and forward and reflected voltages, currents,
and powers at all points in the circuit. Note that the
reflections are *same-cycle* reflections. If the lumped
circuit model analysis differs from the distributed network
model analysis, the lumped circuit analysis is wrong.

> these powers may go up, or they may go down when the reflection
> arrives.

That is true, but the impedance is *VIRTUAL*, i.e. not an
impedor, and is therefore only an *EFFECT* of superposition.
We are once again left wondering about the *CAUSE* of the
virtual impedance, i.e. the details of the superposition
process. Ignoring those details will not solve the problem.

Good thoughts.

By breaking Vg into Vf and Vr, we can explain why very long transmission lines, many wavelengths long, have repeating patterns of inductive and capacitive reactance as if they were lumped components. If Vf and Vr work for long lines, they should work for short lines.

So far as breaking Vg into many sequential/different Vf and Vr, we usually need to do that. Cecil chose our simple example to prevent re-reflection (reflection of the reflection) but even then it is apparent that the voltage source will have a reactive component.

I understand the delemma here. It is like trying to both fill and empty the bottle at the same time. We can't do that with physical objects and we like to think of energy as if it were a physical object. So how can energy seemingly flow into a line at the same time it flows out?

Of course one way would be if Vf actually did reflect from Vr. A reflection beginning at the point Vg, then propagating down the line as an artifact of the original wave. So far as I have been able to figure, the result is the same as when we think of both Vf and Vr as actual waves, which are much easier to follow and calculate.

> > Would it help to consider that before the "reflection from the short" arrives, power arrives via the transmission line path but the impedance is 100 ohms for our example, composed of Rs = 50 ohms and transmission line = 50 ohms? After the "reflection from the short" arrives, the impedance drops to 70.7 ohms so the power to the circuit goes up (assuming a constant voltage source). How can this happen if power is not carried via the "reflection from the short"?
>
> It goes up because the impedance presented by the transmission
> changes when the reflection returns. This change in impedance
> alters the circuit conditions and the power in the various
> elements change. Depending on the details of the circuit,
> these powers may go up, or they may go down when the reflection
> arrives.
>
Your comment almost makes the altered impedance sound like a resistance, probably not quite the picture you want to convey. I think of power to Rs coming via two paths, one longer than the other. In my mind, the changed impedance is the result of two power streams merging back together.

The impedance found when the reflection returns is dependent upon the line impedance, length of line, and conditons at the point of reflection. The length of line is measured in terms of time and wave velocity. While this is strong evidence supporting Vf and Vr, it does not rule out reflection between wave components.

I don't know how many people have seen an railroad engine starting a train from stop, when there is a small gap between each of the cars. You can hear each of the cars bumping the adjacent car in a chain reaction going from engine to the end of the train. Clearly, the reaction has a velocity of travel. Our EM waves could do the same thing but we would never measure anything except the the resultant wave.

Thanks, Owen. Actually, the error I was thinking of was not the Q,
since both a good hairpin and a good helical coil will have Qu's very
much higher than the loaded Q of the matching network -- but rather of
the slope of reactance versus frequency, since the hairpin is a
transmission line and will presumably show a sharp resonance at a
different frequency from the coil's self resonance. But that error
should also be small--negligible as Wim notes.

Cheers,
Tom

> store energy.

"In" is an oxymoron for the lumped circuit model.
The lumped reactance exists *at* the same point as
the source because everything is conceptually lumped
into a single point.

In the real world, circuits are never single points
and there exists a frequency at which distributed
network effects cannot be ignored. In reality,
distributed network effects occur for all real
circuits but they can often be ignored as negligible.

The two inches of wire connecting the source to the
source resistor has a characteristic impedance and
is a certain fraction of a wavelength long. If it is
not perfectly matched, reflections will occur, i.e.
there will exist forward power and reflected power on
that two inches of wire.

>> For the 1/8WL
>> shorted line, there appears to be 125 watts of forward
>> power and 25 watts of reflected power at points on each
>> side of the source.
>
> Not if there is no transmission line.

Aha, there's your error. What would a Bird directional
wattmeter read for forward power and reflected power?
Consider that short pieces of 50 ohm coax are used
to connect the real-world components together.

Or chose any characteristic impedance and do the math.
You will discover something about the real world, i.e.
that you have been seduced by the lumped circuit model.

> Perhaps. But I don't need more examples where the
> powers balance. I already have the one example where
> they don't.

And that one example is outside the scope of the
preconditions of my Part 1 article. Let me help you
out on that one. There are an infinite number of
examples where the reflected power is NOT dissipated

in the source resistor but none of those examples,
including yours, satisfies the preconditions specified
in my Part 1 article. Therefore, they are irrelevant
to this discussion.

> But there are no component powers in the source. It
> is a simple circuit element.

No wonder your calculations are in error.
Perform your calculations based on the readings of
an ideal 50 ohm directional wattmeter and get back to us.
Hint: Mismatches cause reflections, even in real-world
circuits. The reflections happen to be *same-cycle*
reflections. The simplified lumped circuit model, that
exists in your head and not in reality, ignores those
reflections and thus causes confusion among the
uninitiated who do not understand its real-world
limitations.

> 73
>
> Tony I0JX

Hi Tony,

I would be happy to have a look at the file and add the hairpin if you wish. But I can also guide you through doing it yourself. It should be quite easy. Simply click on the "> Trans Lines" button, the second one below > Sources in the main window. Specify the first end the same as the source--perhaps 50% along wire 2, assuming the D.E. is wire 2. That end will then be in parallel with the source. You can type "S" in for the other end's wire #, or if you click in the End 2 Wire # box, you should see a list of "open" and "short" and you can select "short" there. Then enter the length, Z0, velocity factor (1) and loss. Reverse or normal doesn't matter since only one end is connected.

In as much as the hairpin actually IS in the field of the antenna, and couples to it to some degree, there may be a small error in using the EZNEC transmission line, instead of entering it as wires, but for a short stub I would not expect that to be a significant issue. I do know that the 1/4 wave stub used to separate elements of a collinear does couple to the antenna fields and that coupling is a significant factor in the performance of the antenna--or at least that is what R.W.P. King tells us.

And...thanks much for the interesting discussion topic. I learned a few things from it.

Cheers,
Tom

> missing energy go?

Hint: Missing energy is impossible except in your mind.
Just because you are ignorant of where the energy goes
doesn't mean it is missing. It just means that you fail
to understand interference. Have you not read Hecht's
Chapter 9 on "Interference"?

Obviously, interference is present and there is *NO*
missing energy. I have previously listed the possibilities
at least four times so will not bother listing them again.

> Just another example of why assigning too much reality
> to the imputed powers of the components of superposition
> is misleading.

Just another example of ignorance in action. Waves
possess energy that cannot be destroyed. Just because
you cannot track it doesn't mean it cannot be tracked.

> In other examples, you have suggested inserting a zero length
> transmission line to aid analysis. Why not insert a zero length
> transmission line with an impedance to produce the desired
> reflection?

What would be the characteristic impedance of a length of
transmission that caused a reflection coefficient of 1.0?

> No one has said there is zero energy. Only that there is
> zero energy flow. For energy flow, one needs simultaneous
> voltage and current.

Vfor/Ifor = Z0, Vfor*Ifor = Pfor = EforxHfor
If an EM wave exists, it is moving at the speed of
light and transferring energy. For Z0 purely resistive,
Vfor cannot exist without Vfor/Z0 = Ifor. Vfor is
always in phase with Ifor.

> Assigning too much reality to component signals is
> seriously misleading.

Assigning reality to the components of superposition
is seriously misleading???? Can we therefore throw
out the entire principle of superposition?

> Until one can grasp the simplicity of a transmission line,
> moving to the complexity of free space offers nothing but
> obfuscation.

It is obvious that you have many things you desire to
hide inside that black transmission line to which we
are not even allowed to attach a directional wattmeter.

Since you are incapable of explaining what happens in
free space for all to see, why should we believe that
you have figured out what is happening inside a
transmission line where everything is hidden from view?

Until one can grasp the transparency of free space,
moving to the opaque transmission line where all kinds
of important things are hidden from view offers nothing
but obfuscation.

What I was maning to say that is easier to determine the correct capacitance (just using a variable capacitor) rather than the correct inductance (using a sliding short on the hairpin). Once one determined the correct value, the variable element should anyway be replaced with an equiavalent fixed element

> would yield the 'wrong' answer?

ABSOLUTELY NOT! I said that other impedances do
not meet the specified preconditions for my
Part 1 article so the answers are irrelevant,
not wrong.

If a 50 ohm Z0 and 50 ohm load is specified, do
other Z0s yield wrong answers? Of course not.
Those answers are merely irrelevant to the
specified preconditions.

> I don't recall changing anything. I'm still with
> Fig 1-1 from your paper, which did not include
> non-existant transmission lines.

You have not proved any errors exist in my Part 1
article. You keep trying to change the specified
preconditions from average power to instantaneous
power but that is simply unethical.

> Did you not say that adding 1 wave length of transmission
> line does not alter the conditions? Are you now saying

Thanks on you guidance. My hairpin is a U of aluminum tube connected directly to the antenna feedpoints. The U center is connected to the boom.

The hairpin tube diameter is about 0.8 cm. The three sides of the U are approximately 35 cm, 10 cm and 35 cm. I presume that I shall enter 35 cm as the transmission line length, but how to calculate Z0? Moreover what about the velocity factor, perhaps 0.98 for a tube in open air?

Would you have a formula at hand?

Thanks and 73

Tony I0JX

In the interesting case of a current node on an infinite-SWR line, it appears we do have energy flow without any current, and therefore without power. Energy flows into the node from both directions in equal amounts at the same time, and out to both directions in equal amounts at the same time. What we don't have is *net* energy flow at the node. Likewise, there's charge flowing into the node from both directions, and out in both directions, which results in the zero net current. I don't believe that's the same as saying there's no energy or charge flow at all, even though the power and current are zero. And it's not necessary to separately consider forward and reverse waves of current, energy, or power in order to observe this -- it can be seen from looking only at the total charge or energy.

Hi Tony,

Since the spacing is so large (10cm), it may be better to enter the
hairpin as wires in the model. It might be interesting to compare the
results between wires and a transmission line. First the wires:

I assume that the D.E. is one wire in the model you have now. I
suppose it has an odd number of segments, so that the source can go
just in the middle. I'm assuming the hairpin parallel tube segments
are center-to-center 10cm apart. I will assume the D.E. is currently
250cm long, all at some x value, and y extending from -1.25m to
+1.25m, as one "wire" of some diameter. To be able to connect the
hairpin at the right places, we need wire ends at -.05m and +.05m, so
we can change the D.E. wire to be one segment between y=-.05m and +.
05m, and then add 2 wires the same diameter as the D.E., one from
y=-1.25m to -.05m, and one from y=+.05m to +1.25m, and each with about

half as many segments as the original D.E., all at the original x value. (Or exchange x and y if I have guessed wrong.) So if the original D.E. had 11 segments, put 5 segments on each of the two new wires. Now add three new wires to represent the hairpin U. Assuming the hairpin is oriented perpendicular to the plane of the antenna, it will be all at the same x value as the D.E. I'll assume the antenna is at z=0. So the wires will have ends at x,-.05,0;x,-.05,.35 and x,-.05,.35;x,+.05,.35 and x,+.05,.35;x,+.05,0 -- and all with diameter 8mm or .008m.

For the transmission line model: the diameter (8mm) and spacing (100mm center to center) tells me the line impedance is about 380 ohms. It should be OK to assume VF=1.00, if there is no insulation around the tube. One problem is that the short across the end is not really a short--it is more an inductance. We could go to the trouble of calculating the inductance and putting that as a load on the end of the transmission line instead of just a short, but it should be a good approximation to just lengthen the line by half the length of the "short"; I would enter the line length just as 40cm instead of 35. (I won't be surprised if Owen pops in here with either a confirmation or a better suggestion!)

Cheers,
Tom

4079. Optimum wavelength % for a stick antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-09 19:39:01 UTC
From: usmcbrat <president@whitehouse.gov>
Message-ID: <pX8Lj.19131$4O1.19019@trnddc03>
Source record: 26203

Hi All:

Is there an optimum % length for an antenna when the antenna is a simple straight stick? 1/4 wave... 1/2, 5/8, full wave? Does it differ depending on wavelength? If size is not a consideration, is a full wavelength preferable?

I've Googled around a bit but haven't found a good explanation yet.

Art Unwin, KB9MZ wrote:
"Regards to all as I depart----."

Would Art cut and run if his claim of an antenna for HF that deployed in the size of two shoe boxes and that performed as well as an antenna that deployed to a significant fraction of a wavelength were so? I think not. It has always been a fairy tale.

Truth is, a small antenna has a small radiation resistance. Ratio of the radiation resistance to the antenna`s total resistance predicts its efficiency. Available materials mean we must use large antennas to get efficiency.

Don`t go away mad, Art. Your stories are entertaining and make us think. Just don`t expect baloney to pass unchallenged.

Best regards, Richard Harrison, KB5WZI

Thanks Tom,

I did the EZNEC model exactly as you suggested, but I now have another doubt (I must re-read the EZNEC help one of these days...)

I would say that I shall still feed the driven element at its center, and not separately feed the two junctions between the hairpin and the driven element

Is that right?

There's no single "optimum" length; every length has its own
characteristics, and each length is better for some purposes than
others. I suggest that you visit your local library and check out a copy
of the _ARRL Antenna Book_. It'll provide a good basis for learning
about this interesting topic.

Hi Tom,

Warning bells sound to me when applications call for reactors fabricated from TL sections. Not to say that are always bad, but they aren't always good, and they bear examination.

I think that may have been in Tony's mind over the matching network.

In the case of the hairpin, fabricated from substantial material, it looks good in this application. Because the line section is so short, inductive reactance is almost linearly proportional to length, and self resonance of the line section itself is nearly a decade higher.

My experience with one of the HyGain (now MFJ) 2m Yagis was that VSWR was stable with weather and over time. I had taken some care to exclude air + water from key connections, in fact I replaced all the fastners used for electrical connection with SS when the beam was less than a year old because of corrosion. Tweny years later the remaining fastners used only for mechanical retention required replacement due to corrosion. But, after the first rework, the matching system seemed robust (bird proof) and reliable.

I have used them since on home made antennas with good success.

Owen

If you're talking about a vertical whip antenna, you may want to look at a
5/8 wave - but you would need to add a little coil at the bottom to match
impedence to 50-ohms.
I read somewhere that that the pattern of a vertical antenna improves as the
length approaches 5/8-wave.
Picture the pattern like a small balloon full of water sitting on a map -
and as you increase the length of the whip, you press down on the
water-balloon - making its coverage more horizontal - thus covering more
area. Some of the radiation that would have gone up now goes out.
And a dipole with 5/8 wave on each pole would make it more directional as
well.
I don't have references to point you to, just going by memory - which may -
or may not - be intact.

> By breaking Vg into Vf and Vr, we can explain

I am not sure that 'explain' is the correct word. It certainly
provides
a convenient technique for computing the voltate and current along the
line, but there are other ways to compute the result; differential
equations being one other way, though less convenient. But I am not
convinced that a convenient technique for solving the problem is
necessarily an 'explanation of why'.

> why very long transmission lines, many wavelengths long, have repeating patterns of inductive and capacitive reactance as if they were lumped components. If Vf and Vr work for long lines, they should work for short lines.

This is true. But when we descend to zero length lines, as some have
done, the rationale becomes quite a bit weaker.

> So far as breaking Vg into many sequential/different Vf and Vr, we usually need to do that. Cecil chose our simple example to prevent re-reflection (reflection of the reflection) but even then it is apparent that the voltage source will have a reactive component.

I still think of a voltage source as just being a voltage source, not
something
with resitance, reactance or impedance.

>
> Of course one way would be if Vf actually did reflect from Vr. A reflection beginning at the point Vg, then propagating down the line as an artifact of the original wave. So far as I have been able to figure, the result is the same as when we think of both Vf and Vr as actual waves, which are much easier to follow and calculate.

I agree that the final results are the same. The intermediate results
can
mislead in different ways.

> > > Would it help to consider that before the "reflection from the short" arrives, power arrives via the transmission line path but the impedance is 100 ohms for our example, composed of Rs = 50 ohms and transmission line = 50 ohms? After the "reflection from the short" arrives, the impedance drops to 70.7 ohms so the power to the circuit goes up (assuming a constant voltage source). How can this happen if power is not carried via the "reflection from the short"?
>
> > It goes up because the impedance presented by the transmission

>
> Your comment almost makes the altered impedance sound like a resistance,

Impedance does have some similarity to resistance, but only for
single
frequency sinusoidal excitation, though I was not trying to say that.

> probably not quite the picture you want to convey. I think of power to Rs coming via two paths, one longer than the other. In my mind, the changed impedance is the result of two power streams merging back together.
>
> The impedance found when the reflection returns is dependent upon the line impedance, length of line, and conditons at the point of reflection. The length of line is measured in terms of time and wave velocity. While this is strong evidence supporting Vf and Vr,

The technique of breaking actual voltage into Vf and Vr certainly
works. But

I would not say this is evidence for the existance of Vf and Vr,
merely agreement
with superposition.

One of my text books drags the reader through the solution using
differential
equations, and then introduces Vf and Vr as a simpler way to solve the
problem.
The student is truly happy from learning that diffyQs will not be
required.

> it does not rule out reflection between wave components.

I think I would be tempted to cut the node down the middle creating
two nodes with no current flow or energy flow between them.

One thought experiment I rather like is the infinite SWR ideal line.
Cut the line at all the current zeroes. The voltage, current, and,
I'd suggest, the energy distribution do not change. The line can
be re-assembled, again with no change.

Those who argue that energy is crossing the node, have to explain that
the cut has completely changed the mechanism that keeps the net energy
in its place, but the voltage and current distributions remain the

same. I prefer the basic circuit theory tenet that one can cut a line carrying no current without impacting the circuit. This leads to a model with no energy crossing the node.

:-) Yes, indeed. I just this afternoon fabricated a 500MHz LPF that I wanted to give about 40dB attenuation up to several GHz. My design was a 5th order elliptical, so I had two parallel tanks for the series paths and three shunt capacitors. Because the coils (10nH and 15nH) are so small, I though about using a shorted stub instead, but then realized that my shorted stub would look like a short when it was 1/2 wave long, not a good thing to have as a series element at a frequency you want to block. Probably would have worked OK since the two stubs were different and wouldn't have the same resonance frequency; and by the time you reached that freq., the shunt caps would be pretty effective on their own. Anyway, it works fine with tiny coils. Thank goodness for good microscopes.

Cheers,
Tom

You sometimes use three. Discussions of ghosts have at
least three. Not so foolish, methinks.

Actually, the transmission line input impedance is quite real,
formed from distributed capacitance and inductance. Like most two
terminal circuits, it can be reduced to simpler form.

Hi Tony,

I can understand your confusion and doubt. I hope this says it in
clear terms:

In the revised model with the hairpin done as three wires, the
original D.E. single wire was replaced by three wires: a 10cm long
center section which should have the source in its center, and a
"left" and a "right" outer section. Those three sections are three
separate wires. The reason to break the original single wire into

three wires is so that there will be wire "ends" to connect the hairpin wires to. You can only connect wires at their ends, even though they have multiple segments. So yes, in the new model the source is just in the middle of the wire which is the middle section of the D.E.

Cheers,
Tom

It would read something completely different if it was
calibrated for 75 ohms, though the difference between
Pf and Pr would be the same.

But that is not the circuit of your Fig 1-1.

> Or chose any characteristic impedance and do the math.

As long as you agree that the imputed energy in the
reflected wave is not dissipated in the source
resistor; and only claim that the imputed average
power in the reflected wave is numerically equal
to the increase in the dissipation.

>

Well there's a plan. Measure everything in a
circuit with a directional wattmeter. You first.
Start with Fig 1-1.

But you'll have to choose the calibration impedance.

I'd suggest 100 ohms for the section between the
source and the source resistor because the source
resistor and the line initially present a 100 ohm
impedance and you would not want any reflections
messing up the measurements.

> Hint: Mismatches cause reflections, even in real-world

We should explore this new world. Please discard your
voltmeter, ammeter, oscilloscope, ... All you need
is a Bird wattmeter.

An ideal voltage source has, by definition, zero impedance, which means zero resistance and zero reactance. No amount of current you put into it or take out of it will alter its voltage. The ratio of voltage to current at its terminals is the impedance of the load which the source sees, not the impedance of the source. If a source used in an analysis has finite resistance, it's not an ideal voltage source.

When you cut the line, you introduce an open circuit
where none existed before. Everything obeys the
distributed network model, at least conceptually.

Before you cut the line, there is no physical
impedance discontinuity and therefore no
reflections. You have to invent complete new
laws of physics for that one. I'm not against
you inventing new laws of physics but you need
to invent them before, not after, you use them. :-)

Between 9.5 and 10.5 seconds, 1.983607 J (average 1.983607 W)
of energy flows. By 'interference', I think you are suggesting
the missing power from 4.5 to 5.5 appears as excess power
between 9.5 and 10.5, thus satisfying your conservation of
energy requirement. But where was the energy stored for
5 seconds until it could be delivered.

Or, more intriguing, between 0 and 1 second, 1.935466 J
(average 1.935466 W) of energy flowed, but the sum of
the powers of the two constituents was only 1 J (average

1 W) in this interval. Where did the extra energy come from?
Was it borrowed from the future? It did not come from
the past since the generator was not yet on.

That is why I pose the question, hoping for someone to
describe the mechanism that the energy for the flow that
is happening now can be borrowed from the future.

But what happens if the generator is turned off before
the future arrives? Where did the extra energy come from
then?

Exactly. With the source impedance being zero, you can use
any impedance line you like.

Well, you can solve these problems in other ways.
Superposition is not required, but it is certainly
convenient. I would not throw it out just because
the constituent powers do not necessarily have

any real meaning. I would just make sure I used
it in ways that did not mislead.

Actually, I have a pretty good grasp of what is happening
in free space, and it is all available to you by extension
from the behaviours of the one dimensional transmission
line. But there is little point in going there until the
transmission line is understood. Three dimensional free
space has much too much wiggle room. And you are an
expert at wiggling.

I didn't say virtual impedances are not real. I
said they are not causes of anything and are,
instead, effects of superposition incapable of
causing anything in the complete absence of a
physical impedance.

You have for a long while now, confused cause
and effect. Maybe you should review the three
separate definitions of "impedance" given in
the IEEE Dictionary.

And yet....

The voltage distribution on the line, the current
distribution on the line and the energy distribution
on the line has not changed one iota.

This new physical impedance discontinuity has not
had any observable effect. All it seems to change
is the reflection of the unobservable forward and
reflected waves.

But the voltage distribution on the line, the current
distribution on the line and the energy distribution
on the line has not changed one iota.

These reflections can not be so important if they
can not be observed.

My ethical standards will not allow me to lie about
technical facts in evidence. You cannot bully me
into doing so.

When the average interference is zero, all of the
average reflected energy is dissipated in the source
resistor. It is true for all examples of Fig. 1-1.
You have not presented even one example where
that is not a true statement.

> We should explore this new world.

There's no new world. All I am presenting is the
distributed network model which is lots older than
I. What you should present are your new laws of
physics that contradict the distributed network model.

There is no extra energy. Constructive interference is
impossible without that supply of energy.

It is the exact opposite. There is no point in inventing
new laws of physics for transmission lines if those new
laws don't work in free space.

So please present an example of EM waves reflecting off
of other EM waves in free space. Do you really think the
energy in the standing wave beam of a laser is reversing
direction and momentum every cycle?

In one case the wave energy changes direction and
momentum at the physical discontinuity. In the
other case, there exists nothing to change the
wave direction and momentum.

> This new physical impedance discontinuity has not

Yes, exactly in agreement with the laws of physics.

> But the voltage distribution on the line, the current
> distribution on the line and the energy distribution
> on the line has not changed one iota.

Please present your new laws of physics that allow
EM waves to reflect off of EM waves in the complete
absence of a physical discontinuity. And please
demonstrate such in free space so we can see the
results.

But the distributed capacitance and inductance
are physical impedances.

Neither 'virtual impedance' nor 'impedance, virtual'
are in the dictionary (at least the 7th Edition).

But all you have demonstrated is that the imputed
average power in the reflected wave is *numerically
equal* to the average increase in the dissipation
of the source resistor. Which is good, as long as
that is all you claim. Which it some times seems
to be, especially when you qualify with "interference
is zero".

Finer grained analysis shows that the imputed
energy (not average) in the reflected wave is not
dissipated in the source resistor. The trouble
is, sometimes you agree with this (when you
invoke that interference is present), but other
times you don't (see your response to the opening
paragraph). It is this flip-flop that makes your
actual position difficult to discern.

For the example under discussion, the signals start with
'constructive interference'. There has not yet been an
opportunity for desctructive interference, which happens
later. So where does the extra energy at the start come
from?

> > But what happens if the generator is turned off before
> > the future arrives? Where did the extra energy come from
> > then?

Exactly. This is the problem with your model. The extra
energy (i.e. the energy greater than that in the sum of
the spectral components) is present, but your model does
not have somewhere for this energy to come from.

> > Actually, I have a pretty good grasp of what is happening

There are no new laws of physics. There is just the
opportunity for a better understanding of what is
happening. This better understanding applies in free
space as well. It is just much easier to obtain this
better understanding on the transmission line and then
move to free space.

> So please present an example of EM waves reflecting off

Why does this thought make you uncomfortable? Is it because
you are trying to commingle the wave explanation with the
partical explanation? These are a duality. You use one
or the other, but not bits from each at the same time.

As I expected, you claim that the situations are
completely different. And yet the voltage, current
and energy distributions are identical. There are
no observable differences. And yet you claim they
are *completely* different. And yet there are no
observable differences. And yet....

Tis a puzzle, isn't it.

And we know from circuit theory that we can cut
a conductor carrying no current without affecting
the circuit. Why should it be different here?

Again, not my claim. But using your previous approach
for analysis, perhaps we should insert a zero length
line of the appropriate impedance to provide the cause
for the reflection, if you insist on a reflection.

But they are constant, i.e. there is no physical
impedance *discontinuity*. The reflection coefficient
inside a homogeneous piece of transmission line is
(Z0-Z0)/(Z0+Z0)=0, i.e. there can be no reflections.
The reflection coefficient in free space is
(1.0-1.0)/(1.0+1.0)=0, i.e. there can be no reflections
in free space.

> Neither 'virtual impedance' nor 'impedance, virtual'
> are in the dictionary (at least the 7th Edition).

"Virtual" essentially means that no physical impedor
exists. The virtual impedance definition is covered
by definition (B), the ratio of voltage to current
which *causes* the impedance. A virtual impedance
is an *effect*, not a cause.

It is the joules in instantaneous power that must
be conserved, not the instantaneous power. There
is no such thing as a conservation of power
principle yet all you have presented are power
calculations. "Where's the beef?"

How many joules are there in 100 watts of
instantaneous power?

Keith Dysart wrote:
> For the example under discussion, the signals start with
> 'constructive interference'.

If the source is local and capable of supplying energy,
all is well and good as I have said many times before.
But constructive interference in the absence of any
source of energy is impossible.

That is exactly why you need to perform your calculations
with the source removed from the source resistor by one
wavelength of ideal 50 ohm transmission line. If you come
up with a violation of the conservation of energy principle,
something is wrong with your math.

If two coherent signals need constructive interference and
energy is not available, the two signals react as if they
were not coherent, i.e. Ptot = P1 + P2. Physics 201.

> Exactly. This is the problem with your model. The extra
> energy (i.e. the energy greater than that in the sum of
> the spectral components) is present, but your model does
> not have somewhere for this energy to come from.

Yes it does - as I have explained about 5 times now. If a
local source is present, constructive interference energy
can and often does come from the source. Why do you find
that fact so hard to comprehend? Sources supply energy -
that's what sources do. An ideal local source can react
instantaneously to any energy requirement.

> There are no new laws of physics.

On the contrary - there are no existing laws of physics
that allow EM waves to bounce off each other yet that's
what you are proposing. You are inventing new laws of
physics to support your (magical) thinking. So please
produce the theory and proof that EM waves can bounce
off of each other.

> That was someone elses suggestion, not mine.

Copout alert! How can *your* reflections at a passive
node occur without EM waves reflecting off of other EM
waves?

> These are a duality. You use one
> or the other, but not bits from each at the same time.

Keith, you have been willy-nilly mixing bits of the
distributed network model with bits of the lumped circuit
model ensuring that your energy equations will not balance.
You are the absolute worst offender of your own advice.

> observable differences. And yet....

I did NOT claim that the situations are *completely*
different. I said that some conditions are different
and some conditions are the same. Voltages and currents
are the same yet there is certainly a difference between
an open circuit and a short circuit. Besides, in the
real world, cutting the line would certainly cause
observable differences.

> Tis a puzzle, isn't it.

Nope, if you were born without your five senses,
you would feel that way about everything in existence.
Why do you deliberately choose to remain handicapped
by ignorance?

A bit of modulation would cure up the mystery for
you. If any modulation crosses the node, it is a
good bet that wave energy is carrying the
modulation. If phase locked TV signal generators
equipped with circulator load resistors are
installed at each end of a transmission line,
the TV signals can be observed on normal TV
sets crossing the standing wave nodes as if
they didn't exist. Removing the modulation
is unlikely to reverse the laws of physics.

> And we know from circuit theory that we can cut
> a conductor carrying no current without affecting
> the circuit. Why should it be different here?

Please prove that a short circuit and an open circuit
are identical.

>> Please present your new laws of physics that allow
>> EM waves to reflect off of EM waves in the complete
>> absence of a physical discontinuity.
>
> Again, not my claim.

Seems your theory requires such. Please explain how
reflections can occur at a passive standing wave node
without EM waves bouncing off of each other.

Energy and momentum both must be conserved. A causeless
reversal of energy and momentum is impossible whether
it is a bullet or an EM wave.

> But using your previous approach
> for analysis, perhaps we should insert a zero length
> line of the appropriate impedance to provide the cause
> for the reflection, if you insist on a reflection.

Please produce an example of
a real world transmission line that would support your
100% reflection. Hint: what would be the Z02
characteristic impedance in the reflection
coefficient equation, (50-Z02)/(50+Z02) = 1.0 ???

I have had the batteries on charge in the MFJ-259Z for over a day now. The jumper inside the unit is on for charging. The batteries were at 12.6V when put on charge and are still 12.6V. The PSU is working fine. Because I can run the unit off the PSU that came with it.

Any ideas on what can be wrong with it now?

Thanks

1] You might want to contact MFJ and see if they can supply you with a schematic of the unit. Usually with minimum knowledge and a Volt/Ohm/Meter, you should be able to check some internal voltages, and or check the operations of transistors/voltage regulators, and or internal fuses.
2] If you don't want to open up the box, contact MFJ and see how much they want to repair the unit.. They seem to be reasonable folks..

>
>Any ideas on what can be wrong with it now?

It certainly sounds to me as if the charging circuit is not working,
or is not working effectively.

12.6 volts is 1.26 volts per cell, which is what I'd expect to see in
the no-load or light-load case of a NiMH with a fractional charge
(maybe half-charged?). The cell voltage will rise, as charging
continues, to as high as 1.4 volts or more (depending on charging
current).

It could be that the charging circuit simply isn't working at all.

It's also possible that the charging circuit is only delivering (by
error or design) just enough of a trickle charge to prevent an
exernally-charged NiMH battery from self-discharging. If the
battery is only receiving 10-20 mA, this would be the case - the
battery will essentially *never* recharge itself completely under
these conditions.

There's a real tradeoff with NiMH cells. Any simple charger which is
capable of recharging them in a reasonable amount of time (say, a day
or less) should *not* be left hooked up to them indefinitely - it'll
overcharge them and significantly shorten their life. Conversely, a
simple charger which *can* be left hooked up for days at a time, will
not recharge a dead battery rapidly enough to be useful.

Charger circuits *can* switch between two charging modes (fast and
maintenance) but it requires quite a bit more complexity.

So... what to do now. My suggestions:

[1] First, measure the voltage across each individual cell in the
battery. If they're all around 1.25 or so, then the cells are
probably OK, and the problem is in the charging.

If you find that most of the cells have a higher voltage, and one
is very low, then that one cell is junk and should be recycled and
replaced.

[2] Get a digital multimeter with small alligator-clip leads. Set it
on its "DC current" scale, remove the charging jumper in the MFJ,

and connect the two leads of the multimeter to the two pins that had been jumpered together (stick a bit of paper between them to prevent the multimeter leads from shorting). Plug the MFJ into its wallwart (with the power switch turned off) and read the current on your DMM. This will tell you how much current is flowing into the battery through the charging circuit (assuming that it's a simple linear charger and not a pulse-charger).

If the current consistently reads zero, then the charger is not working at all.

If it's charging at a rate of below 50 mA, then it's just a maintenance trickle-charger... sufficient to keep charged batteries alive in standby mode, but insufficient to recharge them in any reasonable amount of time. You'll need to do the major charging using an external charger.

If it's charging at 100-200 mA, then it'll take a day or more to fully recharge.

If it's charging at over 200 mA, then it'll recharge effectively in under a day, but should *not* be left hooked up indefinitely... it'll overcharge the batteries and shorten their service life.

Thanks for your clarification that confirms my expectation that I shall put the generator in the middle of the 10 cm-long center section of the D.E..

Everything works fine and, for a reference 200-ohm resistance, I get an SWR of almost 1 not too far away from the frequency at which it actually occurs.

If I may take a bit more of your time, I have noted two inconsistencies:

- with the hairpin EZNEC gives an antenna gain of 12.76 dB but, if I just delete the three hairpin segments leaving everything else unchanged, the gain grows up to 13.59 dB. I am surprised about that result, as I had understood that, in EZNEC, the antenna gain has nothing to do with the way the antenna is fed.

- with the hairpin, at the antenna resonant frequency EZNEC shows an impedance of 200.5 +j2.1 ohm which obviously corresponds to an SWR of almost 1. If I remove the hairpin, at the same frequency EZNEC shows an impedance of 42.4 - 39 ohm which could seem reasonable, but it is actually not. As a matter of fact, by applying the appropriate series-to-parallel conversion formula, that impedance corresponds to the parallel of a 78.2 ohm resistance and a 85.1 ohm capacitive reactance. Resonating the reactive capacitance with an equal (though opposite) reactance hairpin, the remaining resistance would be just 78.2 ohm, that is far away from the 200 ohm EZNEC shows with the hairpin installed.

May I have your opinion?

Hi Tony,

Hmm...very interesting. I hope some others will check in on this with ideas too.

My first thought is that the hairpin conductors are really more a part of the antenna than you may have thought. The current in that 10cm section of the hairpin, especially, is in a direction parallel to the D.E. and to all the directors and to the reflector(s). It will couple to them, and could be changing the gain and impedance some.

I am also surprised by the high resistance you are seeing with the hairpin wires removed. From what you posted before, and from the 3-element NBS and the 6-element designs I ran in EZNEC, I would expect a lower feedpoint resistance than that. If I put a pure inductance in parallel with your 42.4-j39 ohms, I get the same answer as you did, that it moves to 78 ohms resistive.

My offer to look at your EZNEC file is still open, of course. Maybe I could see something in it--I know that I can look and look at something and not see an obvious problem, even when I know perfectly well what to look for.

Also--in the model before you split the D.E. into three wires, did you get a more reasonable feedpoint impedance (with no hairpin, just looking at the D.E. feedpoint)? I think we were expecting something like 19-j58 ohms. If you get that, then I would look for the reason things change (so very much!) when you split the D.E. into three separate (but connected, end-to-end) wires. I can understand a small change but not so large a change. Is the total number of segments for the three wires making up the D.E. still about the same as it was in the original version of the model, with just one wire for the D.E.?

Cheers,
Tom

If your personal mail on the newsgroup is correct, I could send you the EZNEC file of my antenna.

I am also surprised as I would have expected a much lower resistance (as you suggested)

I did the test you have suggested and I noted some change, but not much. With a "solid" D.E., i.e. not broken in three pieces (and without the hairpin of course), impedance is 43.27 - j 40.97 ohm, not terribly away from 42.4 - j39 ohm. In that test I configured EZNEC for 17 segments, whilst when the D.E. was broken in three parts I had used 17 segments for the two outer arms and only 5 segments for the 10-cm center section, due to its much shorter length (I see that result depend somewhat on the number of segments).

The only problem is writing out personal theories is not "proof".
You have not proved anything here. You have only offered
your theory.

>Considering that Einstein spent his whole life searching
> for this and eventually turned

What does Einstein have to do with small 160m antennas?

> I shared it with hams because of their love with respect to antennas
> but that is a love of the past.

I don't love antennas. Period. They are mechanical devices.
I also do not get sentimental about antennas, or antenna theory.

> I am extremely disapointed that hams did not go on this jorney with me
> or even supply encouragement.

Not my job.. If you want to design and use such a device, that's
up to you. You already know what type of antennas I prefer.
Full sized ones.
I have zero use for small sub par antennas.
Besides, I thought you had a ham already testing one.
I imagine most are still quivering with excitement waiting for
the report of that version..

> or may not - be intact.

.64 wave is the length that gives the maximum gain for a single
element. But.. Single 5/8 elements really need a lower 5/8 element
to live up to expectations. Also, some may prefer slightly shorter
to minimize radiation at the higher angles.
If you had an EDZ, the best length for maximum broadside gain
is .64 wave per leg/pole.
But like Roy says, there is really no best element length unless
you have a specific purpose for the pattern a particular length
provides. Any gain is one direction is a loss in some other direction.
IE: the EDZ will have more gain broadside than a 1/2 wave dipole,
but less gain in the appx end fire directions. No free lunches.. :/

Hi Dave

I checked the voltages in all the cells and they were all even voltages.
The batteries should be ok.

I checked the current on the two pins like you said and there was no
reading.

I checked the voltage on the two pins. No voltage on the outside pin and 5
volts on the middle pin.

I checked the voltage coming from the charger and its 18 volts.

I checked the voltage from the + side to the - side of the battery pack with
the charger on and got the 12.6 volts.

I checked the voltage from the + side to the - side of the battery pack with
the charger off and unplugged and got 12.6 volts.

I checked the voltage from the battery pack with the charger on and using
the case as the ground. It was 17.9 volts.

The charger says output voltage 12VDC 300mA 3.6VA.

Hope you can point me in the right direction. Do you know what sort of
voltages I should expect when it's charging properly?

Many thanks

Barrett

If you are really having this much trouble troubleshooting the unit and it
is still under warranty - for a couple of bucks in postage you should send
it back to MFJ for the warranty repairs... If you continue to try and get
into the unit you may end up VOIDing the warranty and then it will cost you
a BUNCH of bucks to get it repaired!

What you're probably seeing is a numerical problem in the NEC calculating engine. It's very fussy about the region near a source, and doesn't like small loops which include a source. You should run an Average Gain check (see "Average Gain" in the EZNEC manual index), which will reveal whether this is the problem.

The double precision calculating engine in EZNEC+ is considerably more tolerant of small loops, but can still have problems with average gain for other reasons.

The transmission line definitely falls into
definition (C), "A physical device or combination of
devices whose impedance as defined in definition (A) or
(B) can be determined." The TL is a combination of
devices, a lot of very small ones, and its impedance
can be determined.

Using 26 pf/ft as a representative value for
RG-58, dividing the 45 degree section into 45
pieces, applying the normal rules for parallel and
series circuit elements, the impedance at the
entry to the line is trivially (using Excel) calculated
to be 50.443 /_ 90. Subdividing into smaller
elements would increase accuracy. If I could remember
my calculus, the exact answer could be derived.

There is no need for forward or reflected waves
at all; just basic AC circuit theory.

The computation using energy instead of power has
also been done (and published here) and found also
to demonstrate that the reflected is not dissipated
in the source resistor.

> How many joules are there in 100 watts of

Obviously. It depends on how long you let the
100 W of instantaneous power flow. Integrate and
the answer shall be yours.

When you modulate the carrier, the resulting signal
has many frequencies. Unless great care is taken
with the choice of modulation frequencies and
carrier frequencies, they will each have nodes
at different places on the transmission line. Without
a common node, there is no place that energy
does not cross, hence modulation makes the
question moot. In effect, the standing waves
of the various frequency components do not line
up. (Remember superposition works, for voltages).

If care is taken with the selection of modulation
frequencies with regards to the carrier, then nodes
can be created on the transmission line and neither
the carrier nor the modulation will cross such a
node.

> If phase locked TV signal generators

That is just too easy...
(50-Z02)/(50+Z02) = 1.0

```
50 - Z02 = 50 + Z02
-2 * Z02 = 0
Z02 = 0
That wasn't so hard, was it?
```

==========
No ,you probably have to return it to the UK importer Waters & Stanton.

I have used the MFJ259 (bought in the USA) for many years with an
external small Sealed Lead Acid battery .
I find it a very useful piece of equipment to test antenna matching
units and resistors/capacitors used for RF purposes . Also stubs and
coax cable.

It is also used whenever a UK Foundation Licence trainee in my area
needs to do an antenna assessment eg plotting the SWR curve of a wire
dipole with the exercise to be repeated with a slightly shorter dipole
,showing a shift of the SWR graph towards a higher frequency.
All this is done with a dipole for 28 MHz.

From: networkrail@mailinator.com
Message-ID: <4dc893d0-2c11-46a5-9489-2b7e9861804f@u12g2000prd.googlegroups.com>
Source record: 26250

Once I get my licence, I would like to get a doublet antenna up to work as many HF bands as possible. The problem is that down one side of my garden there are power lines and at the bottom of the other side of the garden is a two story flat/apartment. If I have the dipole running down the power line side of the garden it will have to slope from about 40feet to about 20 feet. Will this be a problem with regards to the balance of the antenna and cause any problems such as RF in the shack etc?

The alternative is to get some kind of thin pole and have one end of the antenna right outside one of the flats kitchen window which I'm not to keen on.

Any advice appreciated

Peter

Well, that certainly violates the conservation of
energy principle. We know the reflected energy is
not dissipated in the load resistor, by definition.

The only other device in the entire system capable
of dissipation is the source resistor. Since the reflected
energy is not dissipated in the load resistor and you say
it is not dissipated in the source resistor, it would
necessarily have to magically escape the system or build
up to infinity (but it doesn't). You keep digging your
hole deeper and deeper.

Hi Bob

The propagation of radio signals is frequency dependent, not modulation mode dependent. That is not to say that some modulation modes are not better over long distances than others, SSB is better than AM and AM is better than FM. To say that VHF frequencies are always line of sight is also not completely correct. They are propagation modes that can extend the range of VHF signals quite a bit. I have worked stations on 144MHz that were more than 500 miles away. But these are not an everyday thing so it safe to say that most of the time VHF is line of sight. 800MHz is in the UHF band and is even more just line of sight than VHF but they are still propagation modes that can extend the range out to 100s of miles. Line of sight propagation is the reason that VHF and UHF antennas are put up high as it extends the line of sight.

I don't know about availability in Spain, but I used to have a Gap "Eagle" vertical that needed no radials. It's actually a vertical dipole, with a center feed. It worked moderately well and had a fairly small footprint.

I bought it when we moved to a new house because my wife didn't want "all those wires in the yard." :-) After using it for a couple of months I wound up putting up another big horizontal loop--but left the Eagle up. Probably 85% of signals were better on the loop but the Gap Eagle worked reasonably well for a small antenna. HTH!

There are lots of "no-radial" verticals on the market.

Your friend will just have to either find a Spanish retailer or find a
foreign source that will export to Spain.

Without knowing the state of import/export regulations and the general
availability of ham radio gear in Spain, your question is impossible
to answer.

Peter, keep any antennas well away from the power lines--very very important! As far as problems, if you're talking about a classic two-sided wire antenna fed by balanced line (ladder-line, etc.), any problems are likely to be tiny and more theoretical than practical. I've used antennas like that, and big horizontal loops, since 1991, and because they all hang from available supports (trees, mostly), they wander all over, they vary widely in height from one place to another. The great thing about antennas like this is that they don't have to be pretty to work well. :-) Higher will be better, for performance--but don't let that worry you. Put some wire up and see how it works!

(And DO keep it away from the power lines!) GL!

I once had a Hustler 4BTV and a Taylor Radio 4 Band Trap Vertical (at different times.) Both antennas recommended ground radials, but I managed to use them effectively with only a ground rod and worked all states and many DX countries.

Obviously, this is not the optimum way to use either antenna, but given the restrictions I had at those times, they were better than the alternative, none!

My thoughts are, that if the antenna is to be ground mounted, as opposed to roof mounted, a good ground rod (Mine was 4') will make most ground mounted verticals usable.

I can't offer much help for a roof mount unless there is ample metal to connect a ground to.

I hope this is useful info.

Hi Derek,

Your forecasting ability would be better served if you actually did something. One project that comes to mind is your Guru's own design, that he has explicitly revealed here. It is notable for being easy to construct and to erect; and offering boon to every user.

Those "supporters" that have faith in Art's design should be able to give us reports of their own efforts of testing his antenna in his behalf.

But that doesn't happen.

This fair weather enthusiasm can only be attributable to his "supporters" patronizing attitude towards Art where they think of him as a doddering eccentric that needs a chuck under the chin to keep his spirits up. Such is the mawkish sentimentality of your post that survives quoted above.

You write "The only other device in the entire system capable
of dissipation is the source resistor." which is a correct statement. Unfortunately, the circuit is intended to illustrate the absence of interference under special circumstances but an instant analysis shows that all the power can not be accounted for. We can only conclude that interference is present. Not good because the circuit was intended to illustrate a case of NO interference.

Our choice of a voltage source is incomplete because we did not assign it a mechanism to provide a reactive voltage, allowing the source to only apply a sinsoidal voltage without specifying the current or current timing. As a result, reflected power will return to the source resulting in an apparent loss of power to the system and resistor Rs. It is not a magical loss of power, only the result of interference acting within the cycle.

The circuit is very useful to investigate interference more carefully because on the AVERAGE, the interference IS zero. Using spreadsheets, we can see how the interference both adds and subtracts from the instantaneous applied voltage, resulting in cycling variations in the power applied to the resistor and other circuit elements. A very instructive exercise.

Hi Roy,

thanks for the tip.

As a matter of fact without the hairpin the average gain is almost zero, whilst with the hairpin is about -0.8 dB, that correponds to the gain drop I notice. So the problem you had anticipated actually occurs.

I then tried to simulate the hairpin with a proper-length shorted trasmission line and, doing so, the average gain is almost 0. Evidently the program does not like the short hairpin loop.

Tom,

the mistery seems to be solved:

- with the "real" hairpin the program does not yield correct answers, neither in terms of gain nor in terms of impedance. Roy W7EL anticipated that the problem is due to the feedpoint being in a short loop. I did the test he suggested (i.e. calculating the Average Gain) and the result I got clearly showed that there was a problem.

- instead, with the hairpin simulated by means of a shorted piece of transmission, the results are fully consistent. Firstly the gain does not vary with and without the hairpin. Secondly the impedance I read removing the hairpin is 24.5 +j65.37 ohm, a value fully consintent with the pure 200 ohm I get with the simulated hairpin.

At least I learned one should not try to model "real" hairpins.

At this point I would not further bother you, by sending you files that would not tell you much. It was a real pleasure for me to have such an interesting discussion with you and, if I may, I will write you should some other strange situation occur in the future.

Therefore, all power dissipated in the circuit must be dissipated
in the load resistor and the source resistor because there is
nowhere else for it to go. Since the reflected power is not
dissipated in the load, by definition, it has to be dissipated
in the source resistor but not at the exact time of its arrival.
There is nothing wrong with delaying power dissipation for 90
degrees of the cycle. In Parts 2 and 3 of my articles, I will show
how the source decreases it power output to compensate for destructive
interference and increases it power output to compensate for
constructive interference.

> Unfortunately, the circuit is intended to illustrate the absence of

> [AVERAGE] interference under special circumstances but an instant analysis shows

Not surprising since there is no conservation of power principle.

> We can only conclude that

> [instantaneous] interference is present. Not good because the circuit was intended to

> illustrate a case of NO [AVERAGE] interference.

I took the liberty of adding adjectives in brackets [*] to your
above statements. It doesn't matter about the instantaneous values
of power since not only do they not have to be conserved, but they
are also "of limited usefulness", according to Eugene Hecht, since
the actual energy content of instantaneous power is undefined even
when the instantaneous power is defined.

> The circuit is very useful to investigate interference more carefully because on the
AVERAGE,

the interference IS zero. Using spreadsheets, we can see how the
interference both adds and

subtracts from the instantaneous applied voltage, resulting in cycling
variations in the power

applied to the resistor and other circuit elements. A very instructive
exercise.

Instructive as long as we remember that a conservation of power
principle doesn't exist and therefore, equations based on instantaneous
powers do not have to balance. The joules, not the watts, are what must
balance.

Hi Tony,

I suppose you are not using EZNEC 5+. If that is the case, I would be
happy to run your model on the 5+ version with double-precision
calculations, and see if that makes a difference. It should be easy
enough to run it. It it no problem to me, just a fun diversion. And
of course I would be happy to have discussions with you in the future.

Cheers,
Tom

A Cinderella story this is not...
Cinderella (French: Cendrillon) is a popular fairy tale embodying
a classic folk tale myth-element of unjust oppression/triumphant
reward.
Thousands of variants are known throughout the world.
The word "cinderella" means one who unexpectedly achieves
recognition or success after a period of obscurity and neglect.

>
> If you think art has cut and run because his claims are false I

Where is the beef? He sent the antenna to be tested by a ham
on this group. Have the tests been completed? No mention yet..
Either he hasn't had time, the snow hasn't melted, or the tests
have been completed, but the results not divulged by Art.
Take your pick.
BTW, I don't blame the tester if he hasn't had time to mess
with it.. It's not really his job to do Art's work anyway..

Prior Art has only himself for this dilemma of credibility.
A normal person would build the thing and compare it to a
known reference. Repeatably, over a period of time over
various paths, etc. They would not expect other people to
do their work for them.
If he can mount his miracle device on a tower, it seems to me
he should be capable of also installing a 1/2 wave dipole at
the appx same mounting height to act as a reference antenna.
I assume his device is horizontally polarized.
If not, he can use a reference monopole.
He talks of receiving DX with this device. I would hope so..
It's fairly common knowledge that even a very small antenna
can be a good receive antenna on that low freq. You have

such a high overall level that atmospheric noise is going to
be the limiting factor, rather than efficiency of the antenna.
The S/N ratio will not be much less than a full size antenna
under normal semi noisy conditions. Maybe not any less,
unless the noise level is very low.
My 44x44 inch diamond MW loop is very good at receiving,
and it can provide fairly good signal levels. But I'd never be
foolish enough to suggest it would make for an efficient
transmitting antenna.
But judging by the description he provides of his shoe box
size antenna using 22 gauge wire, it's quite possible that
my MW loop would out transmit his antenna on 160m.
After all, it's bigger, and using a whole lot less turns to
tune the antenna.
When Art was listening to his DX, why did he not contact
the station and request a signal report?
Cat got his tongue? 0r maybe he did, and the failure to
communicate was just too great for him to bear, much less
divulge to the world. Only the shadow knows for sure.

Why did Art not have a full size antenna up to have on
the air comparisons with said DX station? Or any
station for that matter..
Does he fear rejection of his antenna by said DX station?
It shouldn't really be an issue, being transmitting is not
required to compare the two.
But you have to at least take the initiative to put up a
reference antenna. Whining to rraa is not going to
get it done.
Woe is Art.

How was the performance of the miracle antenna when
you tried it? How did it compare to a full size reference
antenna? Did you see the same inefficient type of
performance from your version as Art described?
How many people have actually been able to hear you
through the noise using such an antenna?
Do you cheat and let the feed line the bulk of the radiating?
Do you actually work 160m at all?

Oh, you say you haven't tried it at all, but just like to
further the propagation of fairy tales...
I get it now. In other words, you about as full of @#$%
as he is?
I've been choking on his bafflegab for quite a while, so
that would be addfing nothing new to add to the program.
:/
The only thing you have left is to prove us naysayers
wrong. Better get busy. The tooth fairy is not going to
do your work for you and stick it under your pillow while
you count the sheep.

I've already tried small antennas. Except for my mobile
where I have no choice, I have no use for small antennas.
I don't like having to repeat most everything I say two or
three times to get a message through the noise.
I tried a half size dipole on 160m, using heavy high Q
loading coils. It would have eaten Arts miracle whip for
lunch. But to me, it was an inferior radiating device,
and was dismantled after only a short time of testing.
But Art is going to beat that 120 ft long high Q loaded
antenna with a shoe box sized mass of 22 gauge wire,
wound in what I consider a perverted manner...
Chortle....You slay me, you really do.

Forget the conservation of power at your own peril, because we need to depend upon the predictability of waves of energy acting over time to solve these problems. When the instantaneous powers do not balance, we know that we do not yet have the complete solution or complete circuit.

You seem to have forgotten that a voltage source can
absorb energy. This happens when the current flows
into it rather than out.

Recall the equation
Ps(t) = Prs(t) + Pg(t)

When the voltage source voltage is greatr than the
voltage at the terminals of the line (Vg(t)), energy
flows from the source into the resistor and the line.
When the voltage at the line terminals is greater
than the voltage source voltage, energy flows from
the line into the resistor and the voltage source.

At all times
Ps(t) = Prs(t) + Pg(t)
holds true.

Conservation of energy at work. No lost energy.

We have been down that path; the spreadsheet has been
published. The flows of energy described by
Ps(t) = Prs(t) + Pg(t)
always balance.

The integration of these energy flows over any interval
also balance.

Energy is conserved. The world is as it should be.

Speculating that this is your way of asking for an
explantion...
With a shorted line, nodes occur every 90 degrees. These
90 degree nodal points are at different places on
the line for different frequencies because the
wavelengths are different. With the nodes at
different physical locations for the different
frequencies, when you sum the responses for all of
the frequencies there are no longer well defined
nodes.

If the frequencies are rational numbers, then
nodes for the total response will exist at the lowest
common multiples of the wavelengths, but it will
typically take a very long line to find one.

If you can't identify where the energy is stored for those 90
degrees you do not have a complete story. Or you are violating
conservation of energy and therefore have no story what-so-ever.

Conservation of energy means that energy flows must be conserved.
Therefore, conservation of power.

Since the total energies in your equations do not balance either,
there is still a problem with your hypothesis.

It would be helpful, however, if you could actually demonstrate a
system where the energies balance, but the flows do not. This would
settle the matter once and for all. (You won't find one, since
balanced flows are a consequence of conservation of energy).

At least in EZNEC 5+, the Transmission Lines window has an entry for
line loss, in dB/100 feet at a frequency you also enter. But the loss
for your 0.8cm diameter aluminum tubing spaced 10cm is only about
0.06dB/100 feet at 50MHz. It is certainly safe to ignore that,
considering that the loaded Q of the matching system is vastly lower
than the Q of the hairpin line as a resonator.

Cheers,
Tom

4159. An alarming reason to ground

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-12 02:52:30 UTC
From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <go80045jh2pvn90sm3cva6u5gqkqdatshr@4ax.com>
Source record: 26149

I recently moved into this house, actually, on the first of this month we moved in. Last week out of boredom, I setup my FT 857D. It sat on the desk for three days before I finally decided that I wanted to listen to something other than the Mount Mitchell Repeater (145.190). I took a 500 foot spool of stranded wire, (invisible fence wire) and tossed it over a few branches and stung it out about 70-80 feet or so. The spool, still attached, is sitting on top of a stack of firewood about 4 feet off the ground but the wire is run from about 10-20 feet or so. The wire tunes up 30, 40, 20 and 80 meters, but with TVI generated with 80 meters, and the power supply hums on 20 meters. 40 meters tunes up clean and easily.

For the past three days, I have been operating CW on 40 mostly, but a little on 80 after TV hours. Today, I decided to try my hand at 30 meters. The wire tuned up well, I dropped the power to minimum for QRP (abt 5 watts) and I sent out a few CQ Strings on 10.110 until a QSO faded in from the background, so I moved up 1 and tried again. The third sequence brought on a surprise. The alarm, for which we have no access code, sounded off nice and loud.

By the time someone found the control box and dug it out from under all the boxes we have yet to unpack, I clipped off the speaker from the alarm at the ceiling. I managed to acquire a real nice 12v 5 AH SLA battery that registers 13.9v and a speaker that must have been made industrial tough. I haven't tested it four audio quality, but I will.

In the meantime, I took the 8-foot ground rod I had placed by my window two days ago, and pounded it 3.5 feet into the ground before being called to supper. I ran about 4 foot of #8 solid copper wire to the rod from the back of the tuner. I checked the tuning of 30 meters, and where I did have a minimal match, I now had a bad match. I tuned it to the 10.111 where I was, and noticed the noise level had dropped. I tested tuning on 20 and 40 meters. On 40, it is about the same, very easy to tune. On 30 meters, where my power supply had been humming when I tuned it, the supply no longer hummed during the tuning phase. I got no RFI on the TV with 30 or 40, but no one was watching it when I tested 20 meters.

I just tested tuning the wire on various bands. It is difficult to tune on 6, 10 and 12 meters, ok on 15, and tunes easily down through 80 less 60 mtrs which I didn't try. 160 meters tunes, but it is really sharp making it difficult. When I get time, I'll make a ground rod driver and finish driving the rod into the ground.

==========
433.92 MHz is a frequency used for unlicenced low power devices like car key fobs ,domestic oil tank level reporting , remote weather station sensors ,etc , even while this is in the 70cms amateur band.

Buck,
Use some of that 500 foot spool of wire and run a few radials instead of the rod. Works just as well, if not better, Same amount of 'work' involved though, just different.
All 'lop-sided' antennas need a ground to be 'happy'. Putting a ground in dirt usually works better than using the house wiring for a ground (RF wise), as you found out.
- 'Doc

A ground should be above 'clothes-line' height, or below where the lawn mower will catch it. After that, almost anything will work, sort of...

I have two questions. On the power socket on the MFJ-259, there are 3
terminals on this socket.
1. Is the centre pin that is + volts.
2.. Is the negative side pin that connects to the GND track on the board.
3,. Is another negative pin that connects to the chassis.

Are the two negative pins in the power socket connected in anyway inside the
socket itself?

They are not connected on the board.

If I bridge a wire from one negative pin to the other on the socket the
batteries start to charge. I don't want to do this if its bypassing the
problem.

I'm beginning to suspect a bad power socket. What do you think?

MFJ just e-mailed back and said.
got to be a short somewhere in the battery compartment then. or there is a
faulty smt diode or resistor. if you have a way of testing the components,
check around the charging jumper circuit.

Many thanks

Barrett

Of course the board is multi layered that's why the pins look as if there
not connected. I've checked for dry solder joints and they all look ok to me
so I think its some thing a bit more serious than that, so back it goes.

Well you now know that the saying, "Ground is not Ground, the World
Around" has real meaning for your new QTH. RF Grounds are different than
Lightning Grounds or Electrical Grounds, and NEVER should the three be
confused, or understood to be non-Mutually Exclusive.

4172. Linear decoupling traps

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-12 17:54:38 UTC
From: JN <jnxx@vfemail.net>
Message-ID: <4800f763$0$8161$9b536df3@news.fv.fi>
Source record: 26162

I am planning a two band antenna for 30 and 80m using linear traps.
The idea is to build the antenna of zip-cord type line 140ohm vf 0.73.
Trap is made using 1/4 wave shorted stub, decoupling occurs at the open end.
My question:
Is there any difference if the shorted end is pointing to the center or to
the tip of dipole.
Only the stub portion has two wires in parallell, the rest is only one wire.

Hi Derek,

Put it back to me? Talk about passivity. As I said, I see nothing in your reply that actually GOES to any active supporting participation by you, simply maudlin cheerleading. This is fey effort at appearing to be gracious.

I have modeled ALL of Art's contraptions. Art has modeled them all too. I have offered the results of that work. Art rarely offers the results of his work. I have built enough models into wire and aluminum (and foils and coils) to find that they all conform to models within suitable accuracy. Art has built enough models into.... and has to date never expressed how they directly compare. The archives are complete to this record - available to anyone with an actual interest in the topic. The results? Pitifully dull where the imagination is reserved for the rhetoric of claims cloaked in a fog of ersatz academia.

You aren't really interested are you? You can't even answer the simple questions about his designs, nor name one advantage pressed against actual performance shown. What are you here for? Slumming for amusement and Art fills the bill? Just another Troll.

Derek wrote:
"---give me a convincing argument as to why Art`s antenna should not be viable,---."

It may be viable. Light bulb thansmissions have been detected over considerable distances.

From clues, Art`s antenna is a full wavelength of small wire coiled to make a dipole. If equilibrium means two equal coils are used to make the dipole, each contains one half wavelength of wire. Each coil fits (almost) in a shoebox.

Such a dipole doesn`t radiate as a fullwave antenna, although Art`s clue is that his antenna doesn`t radiate perpendicular to the axis. That would be true for a straight fullwave antenna remote from ground. Terman says on page 868 of his 1955 opus:
"The result is a directional pattern in which the maximum of radiation occurs at an angle with respect to the wire axis which is the case shown in Fig. 23-6 is approximately 64 degrees (see Fig. 23-4a)."

I`d wager Art`s antenna radiates more as a halfwave dipole radiates.

I posted an excerpt earlier that said that experimenters had found a short insulating whip could be wound with almost twice the resonant length of wire to make the short whip resonant at about half the frequency for a conducting pole of the whip`s length. British hams were quoted as saying the results were good when heavy wire was used for the coil. One can imagine making a dipole with two such quarterwave pole lengths which is my guess as to what Art did, except for the heavy wire.

A continuous small diameter coil is a radial mode helix, not an axial mode helix. It will radiate radially or perpendicularly like a length of wire replacing the axis of the coil. Its radiating length is only about half the length of wire wound into the coil using the experimental results. A full wavelength of wire continuously loading a half wavelength dipole would have about twice the loss resistance of a straight wire dipole. This explains the wide bandwidth Art clains for his antenna.

Efficiency is radiation resistance over total resistance, (loss + radiation resistance). Radiation resistances for the straight and coiled dipoles are about the same but the higher loss of the coiled antenna makes it something of a dummy load. Low efficiency does not make such antennas not "viable".

B&W has many satisfied customers for its resistance loaded folded dipole. Bandwidth can trump efficiency. Art`s antenna may find similar

favor.

Anyone have this and have had trouble tuning.

I lost the pilot light to the meter (still cant figure out how to get it out. And ever since then it wont tune anything well. Keeps going off tune. My 25 year old DIAWA is back in service and working fine.

I bought the 969 cause it had 6meters.

only lasted about a year.

Ideas ???

Cant find any pits on the roller inductor either.

Scotty W7PSK.

That's obviously easy to demonstrate in a distributed
network system. We can have energy flowing into both
ends of a loading coil at the same time and 180 degrees
later, energy flowing out of both ends at the same time.
The energies balance but the flows are completely
unbalanced and indeed defy the lumped circuit model.

>
> I've Googled around a bit but haven't found a good explanation yet.

Hello,

For a single straight stick (assuming a monopole antenna) and maximum radiation perpendicular to the stick, a half wave has my preference. Reason for that: good compromise between gain and requirements for an RF ground. An electrically end-fed half wave stick has lowest requirements with respect to ground. Disadvantage is you need a matching network to match to about 500...3 kOhms (depending in length/ thickness ratio).

A full wave monopole does virtually not radiate perpendicularly to the stick.

The highest gain over perfect ground gives a 5/8 monopole. In most situations, ground is not perfect and then it is questionable whether the 5/8 monopole will outperform the half wave monopole.

When you may feed the stick in the middle, 2*5/8 lambda gives the highest gain. Note that matching requires inductances. 2*1/4 waves matches easiest to 50 Ohms cable.

A full wave dipole has high input impedance, but also larger bandwidth than a half wave dipole. All dipoles require some form of balun when fed from coaxial cable.

It is difficult/impossible to say what length is optimum for your particular situation.

On Apr 12, 12:56 pm, Richard Clark <kb7...@comcast.net> wrote:
> Art has modeled them all
> too.

I think modeling is how he gets started with these things.
That freaking optimizer program that shows him how to
build a skewed 6 element antenna with the performance
of the usual 3 element. What a breakthrough... :/
I called that particular antenna the "cluster%$#@"....
Then then he abandoned that one and decided to go with the
coil antenna he's pushing now.
Viable? Sure it's viable if you don't mind a puny signal.
Note the Isotron.. To me, not a whole heck of a lot
different than what Art proposes. Arts version may
be slightly inferior though..
And some people do buy and use them.. Mostly
ones with yards the size of clothes closets and have
no other choice but to try small antennas of that ilk.
I doubt any of those users really feel like they are
setting the woods on fire.
I knew a guy here locally that ran one for a while
on 75m. He was able to radiate, but a vast majority
of the people on frequency could not hear him.
I think he retired that antenna after a while.
I suspect he ran out of hair to pull out...
And as mentioned, quite a few QSO's have been
made using dummy load light bulbs.
Usually by accident when they forgot to flip the
switch to the real antenna...
Is a light bulb viable as an antenna?
I suppose.. But don't try to claim it is an efficient
radiator.
To sum.. Art suffers delusions of grandeur induced
by various modeling program optimizers.
This can happen to anyone. But... most people
will verify if the data is true by comparing to known
reference antennas. Art does not do this.
He places unflinching blind trust into these programs.
And they have led him astray from reality.
Woe is Art.

Hi Mark,

My girlfriend some time back could work Alaska from here through her dummy load (for the same reasons you described, not that she chose to do it this way).

I can only imagine that Arthur will re-discover that poor isolation problem and describe it as a "Faraday Paradox Enhancement" with inverse shielding efficiency. It may lead to anti-gravity research that finally disproves Einstein's theory of Brownian motion (Art's final nail in the casket of that historical fraud).

Hi Arthur,

Still peaking at these postings, aren't you?

>has done by accident. Can it be done on purpose?

Use a simple wire or rod radiator tied to the center conductor of the
coax, no radiator tied to the shield, and a length of feedline which
is an even multiple of a halfwave (at the exterior shield's
velocity-of-propagation) back to ground or the transmitter, serving as
a counterpoise?

Peter,

I agree that you should keep the doublet or dipole away from the power line.

Sloping such an antenna will work fine. I have two 75 meter dipoles that slope and they do great. I fed them in the center and keep the feedline going away from the antenna at as close to a right angle as possible.

> unbalanced and indeed defy the lumped circuit model.

You are not quite looking at the system correctly.

It is a system with two ports (bottom and top) where
energy can enter or leave, and one element (coil)
which can store energy.

The energy that flows in the bottom either flows out
the top or increases the energy stored in the coil.
The energy flowing into the bottom is equal to
the sum of the energy flowing out the top plus the
increase in the energy stored in the coil.
Expressed arithmetically
Pbottom(t) = Pcoil(t) + Ptop(t)

For the specific situation you describe above:
"energy flowing out of both ends at the same time"
means that the energy stored in the ooil is being
reduced to supply the energy leaving the top and
the bottom. The sum of the energy flows out of
the top and the bottom is exactly equal to the rate
at which the stored energy is being reduced.

Lumped or not lumped is moot.
The same analysis can be applied to a transmission
line. The energy flow into the left is exactly
equal to the energy flow out on the right plus
the rate of increase in the energy stored in the
line.

Energy flows (aka power) do indeed balance, though
you certainly have to correctly pick the flows that
should balance.

It appears to be a counterwound coil on the end of a stick. It isn't all that different than an Isotron antenna. Not quite the same mind you, but in the ballpark.

I haven't built one, but it stands to reason that in the world of electronics, that somoene would have discovered the presumed effect by now via serendipity, if not calculation. Doesn't matter who designed it.

Anxiously awaiting that test report.....

It is not the type of transmission (AM, FM, SSB) but the frequencies that determin the line of sight. For the most part any frequency much above 30 mhz will be line of sight most of the time.

In a few years when the sun spots come back, frequencies up to 50 mhz or slightly more will become more useful for distances greater than line of sight.

There will be times when you can receive transmissions at much greater distances on almost all frequencies. I have worked stations over 500 miles away many times on 144 and 432 mhz. This is not normal, but it can hapen. This is with simple antennas and 25 watts of power. More power and better antennas will give beter results.

Seems to me, the "ground" would cause reflections, turn
that "even multiple of a halfwave" into a standing-wave
antenna, and maybe be more efficient than an Isotron?

Yes, the energy obviously balances but the instantaneous
powers are in opposite directions and therefore cannot
balance.

> Lumped or not lumped is moot.

Energy cannot flow out of both ends of a lumped circuit
inductor. The current is, by definition, exactly the
same at both ends as it is for the lumped inductors in
EZNEC. You might find these class notes informative.

Better be careful about that dreaded word "efficient", especially in
the context of small antennas - Art might take umbrage.

On the basis of the usual "power radiated, divided by power input",
the type I suggested *might* be more efficient than an Isotron... but
only because its losses might be lower. Most of the Isotron designs
I've seen pictured, have a tuned circuit of some sort at the feedpoint
(e.g. a big air-wound coil and a metal-plate capacitor), and there
will no doubt be some losses in this tuned circuit.

I don't know which antenna would have more directional gain at its
primary lobe, or which one would have a stronger signal in whatever
specific angle its operator found most useful at any particular moment.

It is well known that if one builds the wrong model one
will get the wrong answer. You build the wrong model,
then claim that flows do not balance. Unbalanced flows
are the expected result from incomplete models.

Your imcompleteness is that you forgot to include the
energy flow into the electric and magnetic fields around
the coil. When one does not forget this flow, all of
the flows will balance at every instant.

Hi Bob,

John and Ralph pretty much cover some of the familiar turf. I would
add (or perhaps extend what has been said) that atmosphering ducting
can extend that range thousands of miles.

One example that I personally observed (quite literally) was watching
TV programining out of Edmonton and Calgary Canada while I was living
in Colorado Springs, Colorado. There were times I could watch an
entire movie before the duct faded away.

Hi Derek,

Then by your own admission of a very short tenure here, you are quite ignorant of both the scope and depth of this discussion. You feel fully capable of challenging my work that you haven't observed and then saying what you have no experience in is a "clouding of my judgement?" Derek, were you born in the fog?

You really should fade back into the wallpaper and observe for a few years more so that at the end of that term you can make contributions instead of simply continuing your trolling.

You are serving no useful purpose for Arthur, because, again, you would rather dispute what has been accomplished than actually put your hand to any task of work. Your "support" of Arthur is a cheap price of entertainment for gleefully seeing him twist in the wind.

Source record: 26173

Howdy gents,

I thought that the problem of the hairpin or Beta Match was kicked around
way back, please see http://www.k3bu.us/beta_match.htm

Hairpin is shortening the (most important) radiating part of the driven
element where the current is the highest.
The best way to match the long antennas with low feedpoint at the driven
element is to use the folded dipole or Quad element, as I used in my Razor
Beams http://www.k3bu.us/razor_beams.htm

First you shorten the driven element, reduce the effective length, then you
apply lossy matching and then you see less gain and narrower bandwidth.
Folded dipole or quad elements fix that.

Yuri, K3BU.us

Sorry, it may or may not be a coil. It is in a black box
whose contents are unknown. Including the energy flows
inside the black box is impossible. The instantaneous
power into the black box does not balance the instantaneous
power out of the black box.

I had a couple of 100 ft rolls of speaker wire on cardboard reels so I
decided to connect them together as Art had described and they give VSWR

indication much as he described even if I stick them in a metal locker. This may be just what a lot of hams are looking for as it is a very quiet antenna.

g'day Jimmy

welcome to the minority and stand by for Richard to call you a
fool and stupid for listening to Art, I am sure you are the first
among many who will now build the antenna and find out for themselves
instead of listening to those who say if it is not in a book it cant
be done
well done.

How droll!

Perhaps one day you will be able to tell those who are laughing up
their sleeve at this.

Seeing as you are clueless to the implications of this report, I
return to my original question, Derek:
Why are you here?

Probably one of Arts relatives...
It does boggle the mind.. Jimmie gives a report which seems
to indicate it's performance does indeed mimic an air cooled
dummy load, and ole Derek thinks the report claims a success
of the design as an antenna intended to radiate RF.
Cinderella has a mustache, green teeth, and hairy legs
it seems. :(

I'd bet this lack of noise pertains to most any direction and
angle too..
IE: you could spin it round and round, and the noise received
will be puny in any direction compared to any real antenna.
It's possible the pattern may have a couple of nulls where
the noise gets even lower if received from a single source. :/
Art has reinvented the dummy load. And a fairly poorly
designed one at that.. :{
Woe is Art.

Black boxes are an excellent way to set problems which help us
learn about the meaning of theories.

Conservation of energy and its corollary, conservation of power,
is used in a different way for analyzing black boxes than it
is when we analyzed the fully specified circuit in your Fig 1-1.

With the black box, knowing the power function on the two ports,
we can compute the energy flow into the storage elements within
the box. If the flow out of one port is not always exactly
balanced by the flow into the other, then we know that the black
box is storing some energy and therefore that it has some elements
which store energy. In a more typical situation, we do not have
a completely black box, but we know some of its elements. We can
use the balance of energy flows to help us decide if we have all
the elements. If some of the energy flow is unaccounted for, then
we have not yet found all the elements.

If the box is truly opague, then all we can say is that it has
some energy storage elements and that collectively, the flow
into these elements is described by
Pport1(t) - Pport2(t)

The situation is somewhat different in Fig 1-1. All the elements
of the system are completely specified in Fig 1-1 and we used
circuit theory to compute the energy flows. Not surprisingly, they
completely balanced:
Ps(t) = Prs(t) + Pg(t)
Associated with Fig 1-1, there is a secondary hypothesis that it
should be possible to account for another energy flow, the imputed
flow in the reflected wave on the line. The inability to account
for this flow, given the conservation of power corollary to the
conservation of energy law, is a very strong indicator that the

energy flow imputed to the reflected wave is not an actual energy
flow.

Andy replies:

While I agree with the other posters, let me add that "line of
sight"
represents the best possible circumstances, and then only in free
space.

To test this, take your 2 meter handi talki and start up a
conversation
and then walk behind a car, or big truck. Nearly every time you will
be able
to maintain your conversation, even tho you are no longer in "line of
sight".

The environment is so full of reflections that it's like standing
in a hall
of mirrors with a flashlight. Many times you can drive thru a tunnel
without
losing the link. Other times you will lose a signal when you drive
by
light poles. (This is especially noticeable with your FM radio and a
weak signal).

While the radio waves travel propagate thru a non-homogenous
medium with
lots of things present that don't represent 377 ohms, each one of them
causes a reflection that will combine with the original vector, and
can
create sharp nulls or slight enhancement. Also, the combined signals
can effectively make the path of the signal "bend"....

So, while "line of sight" is the simplest answer, I have rarely
found

it to be correct. The close you get to "free space", the more
realistic
it is..... but that hardly ever happens when standing on earth...

Yes, but that is only *NET* energy flow and says nothing
about component energy flow. Everything is already known
about net energy flow and there are no arguments about it
so you are wasting your time. Your equation above completely
ignores reflections which is the subject of the thread.

You object to me being satisfied with average energy flow
while you satisfy yourself with net energy flow. I don't see
one iota of conceptual difference between our two positions.

After hundreds of postings, all you have proved is that
Eugene Hecht was right when he said instantaneous powers
are "of limited utility", such that you cannot even tell
me how many joules there are in 100 watts of instantaneous
power when it is the quantity of those very joules that
are required to be conserved and not the 100 watts.

The limit in your quest for tracking instantaneous energy
is knowing the position and momentum of each individual
electron. Good luck on that one.

I am going to summarize the results of my Part 1 article
and be done with it.

In the special case presented in Part 1, there are only
two sources of power dissipation in the entire system,
the load resistor and the source resistor. None of the
reflected energy is dissipated in the load resistor
because the chosen special conditions prohibit reflections
from the source resistor. Therefore, all of the energy not
dissipated in the load resistor is dissipated in the source
resistor because there is no other source of dissipation
in the entire system. Only RL and Rs exist. Pr is not
dissipated in RL. Where is Pr dissipated? Even my ten year
old grandson can solve that problem and he's no future
rocket scientist.

This thread has one assumption that I find very frustrating, a voltage source that is a steady source of power but can not absorb power. My view is that any source must both absorb and deliver power at some none zero impedance. As justification for this view, I offer that current always flows from high voltage to lower voltage, so a real voltage source would have to absorb energy if the external voltage exceeded the voltage of the voltage source.

While it can be agrued that the ideal voltage source would have zero internal resistance, that argument does not address the fact that power flowing in the reverse direction (into the source, against the source supplied voltage) delivers power into the source. Charging a battery with zero internal resistance is a good example. Another example is the observation that a generator becomes a motor when the externally suppied voltage exceeds the voltage supplied by the generator.

Yes, we can make the assumption that the voltage source can not absorb power at any time, but the assumption takes us into an unreal world and gives answers that are impossible to duplicate with measurements. Some would call that a world of science fiction.

Ahhh, but there is then agreement that energy flows (power) must
be in balance to satisfy conservation of energy.

> Your equation above completely
> ignores reflections which is the subject of the thread.

That it does. We get to that later.

> You object to me being satisfied with average energy flow
> while you satisfy yourself with net energy flow. I don't see
> one iota of conceptual difference between our two positions.

They are quite different. I am quite will to explore (and am
doing so) the concept of imputed energy flow in the reflected
wave. It is just that it comes up short since there is no
explanation of where the energy goes. Were an adequate
explanation to be offered, I would quite accept it.

You should tread back through the posts, the question was
answered.

Three! The source can also take energy from the system.
Since you have overlooked the source, the rest of your
post is quite flawed in its conclusions.

> None of the
> reflected energy is dissipated in the load resistor

Well that is the question, isn't it? It could be in the source.
Or, if it can not be determined where the energy in Pr goes,
then the only other answer is that Pr does not represent an
energy flow. Think Sherlock: "when the impossible has been
eliminated the residuum, however improbable, must contain the
truth."

> Even my ten year
> old grandson can solve that problem and he's no future

I thought I had already addressed that topic when I added the
one-wavelength of transmission line to the example in between
the source and source resistance.

But here's an example that may allow better tracking
of the energy flow. Let's modify my Part 1, Fig. 1-1
to add a 50 ohm circulator and load to the ground
leg of the source. Everything else remains the same.

```
Gnd--1---2---Vs---Rs-----45 deg 50 ohm----------RL
\ /
3
|
50 ohms
|
GND
```

How much power is dissipated in the circulator
resistor?

How much power does the source have to supply to
maintain 50 watts of forward power on the transmission
line?

Does this example answer your questions?

You can probably answer your own question by figuring
out how the light energy in an interference pattern
gets from the dark ring to the bright ring some
distance away. Do you think it happens faster than
the speed of light?

> It is just that it comes up short since there is no
> explanation of where the energy goes. Were an adequate
> explanation to be offered, I would quite accept it.

I am satisfied with the destructive/constructive
interference explanation. That you have come up
short in tracking those component energies is not
unexpected given your prejudices.

If you told me your car disappeared from existence
because you cannot find it, I wouldn't believe you
either.

> You should tread back through the posts, the question was

"It depends" was no answer - that was just mealy-mouthing.

>> In the special case presented in Part 1, there are only
>> two sources of power dissipation in the entire system,
>> the load resistor and the source resistor.
>
> Three! The source can also take energy from the system.

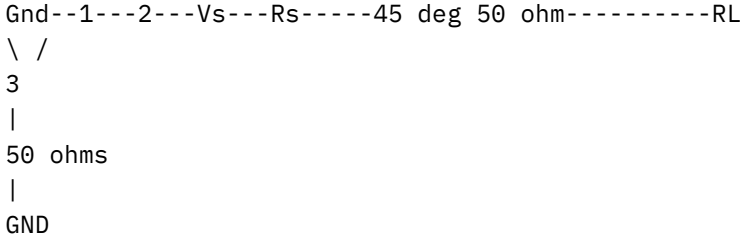
The Vs source has zero resistance rendering dissipation
impossible. I repeat: There are only two sources of
power *DISSIPATION* in the entire system, the load
resistor and the source resistor.

The source can certainly throttle back its output when
there is destructive interference in the source resistor
and increase its output when there is constructive
interference in the source resistor, but it CANNOT
dissipate any power.

> Since you have overlooked the source, the rest of your
> post is quite flawed in its conclusions.

Nope, you are confused. The source can adjust its output
but the source cannot *DISSIPATE* power. As I said, the
only sources of power *DISSIPATION* are the two resistors.
No amount of obfuscation is going to change that.

Perhaps adding a circulator to my Part 1, Fig. 1-1 will
allow you to see things in a clearer light. Of course,
using light would be even better.



How much power is dissipated in the circulator
resistor?

How much power does the source have to supply to
maintain 50 watts of forward power on the transmission
line?

4218. Effect of twisting on twisted pair impedance.

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-14 19:10:43 UTC
From: Wimpie <wimabctel@tetech.nl>
Message-ID: <c2009089-17a4-4183-acd0-a8de2b2420b8@q1g2000prf.googlegroups.com>
Source record: 26190

Hello,

Following link http://qucs.sourceforge.net/tech/node93.html gives an expression for the characteristic impedance of a twisted pair. It also includes a correction on effective permittivity for the twist angle (or twists/length).

I have a document from Universidad de Buenos Aires, www.fi.uba.ar, "Líneas de transmisión" (transmission lines) this document explicitly mentions that the twist angle must be in radians.

However, when assuming twist angle of 45 degrees (0.785 radians, that is tight twisting) and a relative epsilon of 3, the formula gives a decrease of Z0 of less then 0.1% (w.r.t. almost no twisting). This result doesn't match my experience and experimental data from other recourses.

When entering 45 degrees, the result is a reduction of Z0 to 70% of non-twist value, which sounds better to me.

Does somebody have access to the original document (or know from experience) to figure out whether radians or degrees must be used for the formulas in the link mentioned above?

Thanks,

Wim

> This thread has one assumption that I find very frustrating, a voltage source that is a steady source of power but can not absorb power. My view is that any source must both absorb and deliver power at some none zero impedance.

I am not sure why you desire a non-zero impedance. The usual
definition of an
ideal voltage source is that it provides or sinks what ever current is
needed to
hold the desired output voltage. When it is sourcing current then it
is providing
energy. No statement is made about where this energy comes from. When
it is
sinking current, it is absorbing energy. No statement is made about
where
this energy is going.

A non-zero impedance is not required to make any of the above
behaviour work.

If you include a non-zero impedance, then you have a more real world
source
which can often be modeled using the Thevenin equivalent circuit; an
ideal
voltage source (zero impedance) in series with a resistor representing
the impedance of the real world source.

> As justification for this view, I offer that current always flows from high voltage to lower voltage, so a real voltage source would have to absorb energy if the external voltage exceeded the voltage of the voltage source.

This is true.

> While it can be agrued that the ideal voltage source would have zero internal resistance, that argument does not address the fact that power flowing in the reverse direction (into the source, against the source supplied voltage) delivers power into the source. Charging a battery with zero internal resistance is a good example. Another example is the observation that a generator becomes a motor when the externally suppied voltage exceeds the voltage supplied by the generator.
>
> Yes, we can make the assumption that the voltage source can not absorb power at any time, but the assumption takes us into an unreal world and gives answers that are impossible to duplicate with measurements. Some would call that a world of science fiction.

> power *DISSIPATION* in the entire system, the load
> resistor and the source resistor.

You have to read more carefully. I did not use the word
dissipation. This is because there are ways other than
dissipation to remove energy from the system. Just as
the source provides energy and we do not care where it
comes from, it can remove energy and we do not care where
it goes.

Examine Ps(t). You will find that for some of the time
energy is being absorbed by the source. This occurs
when the sign of Ps(t) is negative.

> The source can certainly throttle back its output when
> there is destructive interference in the source resistor
> and increase its output when there is constructive
> interference in the source resistor, but it CANNOT
> dissipate any power.

Since we don't know the internals of the source, we do not
know if it is dissipating or not. But we do know that when
the sign of Ps(t) is negative, the source is absorbing
energy from the system, exactly analagous to it providing
energy when the sign of Ps(t) is positive.

You really should rethink this a bit. When current flows into
a voltage source, the voltage source is absorbing energy.

> How much power is dissipated in the circulator
> resistor?

This circulator, while often used, does not in any way add
clarity.

Changing the circuit changes the results, especially when
you add a circulator which alters rather dramatically the

energy flows.

> How much power does the source have to supply to
> maintain 50 watts of forward power on the transmission
> line?

This depends on the design of the generator and the length
of the line. With a shorted line that is 90 degrees long,
and a generator constructed using the circuit of Fig 1-1, the
source supplies no energy to maintain an imputed forward
power of 50 watts on the line.

My energy equations balance perfectly. Yours are the
energy equations that don't balance in violation of
the conservation of energy principle.

>> "It depends" was no answer - that was just mealy-mouthing.
>
> Except, that it does depend.

Sounds more like religion than anything else.

> You have to read more carefully. I did not use the word
> dissipation.

You have to read more carefully. I used the word
"dissipation" and you disagreed with me. Please
read it again to verify that fact.

> Since we don't know the internals of the source, we do not
> know if it is dissipating or not.

Sorry, the source is, by definition, lossless. All of
the source dissipation is lumped in the source resistance
drawn separately on the diagram as Rs.

> You really should rethink this a bit. When current flows into
> a voltage source, the voltage source is absorbing energy.

But the source is NOT *DISSIPATING* energy because
Rs is not inside the source. Rs is clearly drawn outside
the lossless source so the source generates *ZERO* heat.
I am amazed at the lengths to which you will go to try
to obfuscate the discussion.

> Changing the circuit changes the results, ...

When you get more serious about the technical facts
of physics than you are about saving face, please get
back to us, but please, not before. Everyone is
tired of your delusions of grandeur where the laws
of physics obey your every whim.

> (or twists/length).

They cite the 1971 paper by Lefferson...

Lefferson gives T = tan(theta)/(pi *D)
where T = twist per unit length
theta is "pitch angle" (between wire and line down center of TL)
D is center to center spacing.

he observes that the maximum angle is on the order of 50.5 degrees,
where the wire will tend to break, and that optimum performance is
angles from 20-45 degrees.

Figure 6 in that paper gives the picture... (an angle of zero would be
something like twinlead)

he gives a formula for the actual wire length.. one twist is
pi*D*sqrt(1+1/(tan(theta)^2))

There are some typos in the original paper (Figure 6 and Eq 12).. in the
IEEE Xpress online version, they've been fixed.

>
> I have a document from Universidad de Buenos Aires, www.fi.uba.ar,
> "Lï¿½neas de transmisiï¿½n" (transmission lines) this document explicitly
> mentions that the twist angle must be in radians.

Since figure 2 in the Lefferson paper gives angles in degrees, I assume
that the empirical expression (cited on the QUCS page) is the same as
Lefferson's equation [7] beta=0.25 +4E-4*theta^2

Open form coils for sale.

I have the following new open form coils left for sale.

Air Dux coils

(4) 416T 1/2" dia X 2" long 15t/in $4 each
(3) 432T 1/2" dia X 2" long 30t/in $4 each
(3) 804T 1" dia X 3" long 4t/in $5 each
(2) 816T 1" dia X 3" long 16t/in $5 each

B & W coils

(1) 3008 5/8" dia X 1 7/8" long 32t/in $4

Unknown manufacturer coils (but look like Air Dux)

(3) 1 1/4" dia X 10" long 6t/in $18 each
(1) 1 1/4" dia X 10" long 10t/in $18 each
(1) 2" dia X 10" long 4t/in $18
(1) 2" dia X 2 1/4 long 10t/in $4
(1) 2" dia X 7/8" long 10t/in $2

Lot price totals $153. I will discount if you buy the whole lot.

Prices are plus shipping in CONUS. I need your zip code to figure
shipping.

I thought the addition of a one wavelength transmission line did not address the issue, and only added more reflections. We still need a reason to assume that a voltage source should *not* absorb power.

> 73, Cecil http://www.w5dxp.com

No, I'm sorry but no. I offered the examples of two real sources that will absorb power when the returning voltage exceeds the output voltage (a battery and a generator turned

into a motor). I think that we must allow our voltage source to have that same real property.

I do understand that when we allow the source to receive power, then we need to address source impedance. If we assign a single impedance, then we expect reflections from the source. The simple solution that I propose is to add a source property of absorbing all reflections. This can be accomplished in the real world by making the transmission so long that reflections never return from the source over any reasonable time, or by making the tranmission line sufficiently lossy to absorb reflections. Your example uses the first method.

Does the idea of source receiving power run counter to what you were planning to write in Parts 2 and 3? I am trying to understand why you have such great reluctance to accept that the source could receive power for part of a cycle, especially when it could easily bring the instantaneous power and energy calculations into balance.

Cecil-

I can appreciate that a mobile whip used on an auto, does not have the efficiency of a full quarter wave vertical over an array of counterpoise wires. But it does work.

I want to use a pair of mobile whips as a horizontal dipole. (Or more in the case of the Octopus.) Are you suggesting that such a dipole on 75 or 40 Meters, will not perform as well as just one of the whips mounted on an automobile?

My thought needed more developement. When the source delivers power, we readily accept that the impedance of delivery will be the impedance of the attached circuit. We make the same assumption when a reflection is returned to the source. If we make the assumption that the source has the same impedance as the refection, then no reflection from the source is expected. So yes, I agree with your observation.

A battery converts electrical energy to chemical energy, i.e.
it transforms the electrical energy. A motor converts electrical
energy into physical work, i.e. it transforms the electrical
energy. An ideal source does not dissipate power and there is
no mechanism for storing energy. It seems what you are objecting
to is the artificial separation of Vs and Rs.

> I do understand that when we allow the source to receive
> power, then we need to address source impedance.

The series source impedance is zero. It acts like a short
circuit to reflections, i.e. there are no reflections.
However, there seem to be 100% reflection from the GND on
the other side of the source.

> Does the idea of source receiving power run counter to what
> you were planning to write in Parts 2 and 3?

The source will be shown to adjust its output until an
energy balance is achieved. It will throttle back when
destructive interference occurs at the source resistor
and will gear up when constructive interference requires
more energy.

> I am trying to
> understand why you have such great reluctance to accept that
> the source could receive power for part of a cycle, especially
> when it could easily bring the instantaneous power and energy
> calculations into balance.

There is no known mechanism that would allow an ideal
source to dissipate or store energy. Consider that the
energy you see flowing back into the source is reflected
back through the source by the ground on the other side
and becomes part of the forward wave out of the source.
That would satisfy the distributed network model and
explain why interference exists in the source.

> mounted on an automobile?

The radiation resistance of a 75m hamstick is roughly
about 0.5 ohms. The feedpoint impedance is roughly
about 20 ohms if one subtracts out the ground losses.
Very roughly, that would make a 75m hamstick dipole
have a radiation resistance of about 1 ohm and a
feedpoint impedance around 40 ohms. That's about 2.5
watts out for 100 watts in. I would say that qualifies
for QRP and is actually an improvement over a 75m mobile
hamstick with a measured signal strength that is 12 dB
down from a good screwdriver which itself is about 10 dB
down from a 1/2WL dipole.

Almost any other antenna in the world will beat a
75m hamstick dipole. One can radiate ten times as
much power simply by lengthening it by 50% and using
high-Q loading coils.

You do need to back up a bit and review voltage sources.

When conventional current is flowing out of the positive
terminal of a voltage source, it is usually agreed that
the voltage source is providing energy to the circuit.
This comes from
P(t) = V(t) * I(t)
when V and I are the same sign, P is positive representing
a flow of energy from the source to the other elements
of the circuit.

What do you explain is happening when conventional current
is flowing into the positive terminal of the source?
Is the source still providing energy to the circuit now
that P is negative?
Or is it accepting energy from the circuit, the negative
P representing an energy flow into the source?

Yup, ducting, meteor scatter etc can all provide extended VHF range.
I've only done about 250 miles on 2 meters, though on 6 meters my
farthest contact was about 3000 miles.....did as straight a line
as I could on MS Streets & Trips to 'calculate' that so there may well
be some error.

That was pretty good range for a video signal to carry, Richard; was
that on an older tv that actually allowed you to [fine] tune?

No, the separation of Vs and Rs was made to better understand why no interference would occur in Figure 1-1. found at http://www.w5dxp.com/nointfr.htm.

Here is a quote from Part 1.
"4. Since the transmission line is 1/8 wavelength (45 degrees) long and the load is purely resistive, the reflected wave incident upon the source resistor will be 2(45) = 90 degrees out of phase with the forward wave at the source resistor. This is the necessary and sufficient condition to produce zero interference at the source resistor."

The problem is that the source and reflected waves behave as two power sources out of time by 90 degrees. As a result, the current flows as the result of two sine waves, and can be described by only one sine wave. The one sine wave description necessarily shows that power *does* flow into the source during part of the cycle. Interference techniques are used to combine the two sine waves into one wave so it would appear that statement 4 is incorrect.

It is not the reflections from the source that is the root of the problem. The root is the way two sine waves combine into one wave that runs at a third phase compared to either of the source waves.

I can understand a voltage source that throttles up and down but I can't understand why the throttle all has to be on the plus side. What logic prevents the power from returning to the ideal source from whence it just left?

Our real limit is that only one current can flow for only one voltage for each instant at any place in the circuit. This is how we justify a "one sine wave" description. It is why whenever we have a reflection, we also have interference. It is also the reason that we must have power flowing back into the source for part of the cycle.

Jouko.......you might try to GOOGLE:

"lattin antenna"

That may lead you to useful information.

Lee KA0FPJ

Yes Lee, Google found quite a lot of hits, but they all refer to one 5band
antenna design with no much
real information. So my question still remains open. Could some modelling
program give the answer?
I think those two alternatives differ at least in how much inductive loadind
they are causing to the lower frequency
and so shortening the total length of antenna.

Here was the preceding comment in context which you trimmed:
"I offered the examples of two real sources that will absorb power when
the returning voltage exceeds the output voltage (a battery and a
generator turned into a motor)."

The context was a battery absorbing power when the
charging voltage exceeds the battery's output voltage.
A battery converts electrical energy to chemical energy
during that charging process.

I wasn't talking about my article. I was talking about Vs & Rs
models in general. In the real world, Vs is not separated from
Rs. That only occurs in the ideal model. In the ideal model,
all dissipation is confined to Rs and there is none in Vs.

> The problem is that the source and reflected waves behave as
> two power sources out of time by 90 degrees.

Not quite correct. The problem is that the forward waves
and reflected waves flowing through the source behave as
two power sources out of time by 90 degrees. The source
wave is the net superposition of the forward wave and
reflected wave. An ideal 50 ohm directional wattmeter
in the circuit will not read the source power. It will
read a forward power which is a different magnitude
than the source power. In any case, only Rs and RL
dissipate power in the system.

> I can understand a voltage source that throttles up and
> down but I can't understand why the throttle all has to be
> on the plus side.

It is not all on the plus side. Whatever energy flows, flows.
Sometimes the flow is forward and sometimes it is backwards.
That's the way AC works. If destructive interference is
present, the source reduces its output power. If constructive
interference is present, the source increases its output
power. But the ideal source does not dissipate power, i.e.
doesn't heat up. All of the heat generated in the entire
system comes from Rs and RL.

> Our real limit is that only one current can flow for only one
> voltage for each instant at any place in the circuit.

You are, of course, talking about the *net* voltage and the
net current after superposition of all the components. But

this discussion is not about net voltage and net current.

> This is
> how we justify a "one sine wave" description. It is why whenever
> we have a reflection, we also have interference. It is also the
> reason that we must have power flowing back into the source for
> part of the cycle.

I don't know where you got the idea that energy doesn't
flow back into the source for part of the cycle. Since
it is AC, it does flow forward and backward but none is
dissipated, i.e. none is turned into heat in an ideal
source. An equal amount of destructive and constructive
interference occurs during each complete cycle.

> P representing an energy flow into the source?

Of course there can be an energy flow into the source
and through the source. The point is that the ideal
source doesn't dissipate that energy, i.e. it doesn't
heat up. All of the heating (power dissipation) in the
entire example occurs in Rs and RL because they are
the only resistive components in the entire system.
Any additional heating in the ideal source would
violate the conservation of energy principle.

Good.

> and through the source.

It is not clear what you mean by "through the source".
The source provides or absorbs energy. It does not have
a "through", since it only has a single port.

> The point is that the ideal
> source doesn't dissipate that energy, i.e. it doesn't
> heat up.

It is not obvious why you want to draw a distinction
between elements that remove energy from a circuit by
heating and those that do so in some other manner.

Could you expand?

Is there some reason why you think that it is only
necessary to account for the energy removed from the
circuit by heating?
And that you can ignore energy being removed in other ways?

And how do you know the ideal source does not dispose
of the energy it receives by getting warm? Nowhere
do I find in the specification of an ideal source any
hint of how it disposes of its excess energy. It could
be by heat, could it not?

And the resistor, could it not also radiate some of
the energy it receives? Perhaps even as visible light?
Would that make it less of a resistor because it was
not 'dissipating' the energy?

> All of the heating (power dissipation) in the
> entire example occurs in Rs and RL because they are
> the only resistive components in the entire system.
> Any additional heating in the ideal source would
> violate the conservation of energy principle.

This is quite a leap. The energy flows into the source. We have accounted for that energy. We don't know where it goes from there.

How would it violate conservation of energy if it was dissipated rather than going somewhere else?

In your model, what things could be done with the energy that would not violate conservation of energy? What other things (besides heating) would violate conservation of energy?

Hi:

As I reported some time ago, I compared Hamstick dipoles to a full size dipole at about the same height. The Hamstick dipole was about 20d down from the full size antenna. The 2:1 SWR bandwidth was about 65KHz. They work as an antenna but are in the better than nothing class.

Yes, it was. And I was very much younger (a reverse convergence in this somewhere). This was in the mid-1960s, summer time, antenna pointed generally north, low band TV. The view north was a clear shot to the horizon at a high point of roughly 6400 feet (average terrain at least 6000 feet).

I also worked in a TV shop at the time (summers and weekends) and had experience with 100s of "tuners" for TV. Some were works of art, some trash, and few really helped because Colorado Springs was not a metropolitan area and far from Denver. We did have one advantage however. The local TV transmitters were atop Cheyenne Mountain. That had about a 1 mile height advantage over the average terrain to the east. It was also ground Zero for probably a good percentage of the Soviet nuclear arsenal. I lived, perhaps, two miles from the front doors (direct hit-proof blast doors, those) of NORAD.

Keith Dysart wrote:
> It is not clear what you mean by "through the source".
> The source provides or absorbs energy. It does not have
> a "through", since it only has a single port.

Good grief! The source is a two terminal device
with one terminal tied to ground. Since it has
a zero resistance, an EM reverse wave can flow
right through it, encounter the ground, and be
100% re-reflected by that ground. I have already
explained that. Did you bother to read it?

If you put an ideal 50 ohm directional wattmeter
between the source and its ground, what will it read?

dir
GND---watt----Vs--Rs----------RL
meter

Did you bother to analyze this configuration?

Rs=50
----50-ohm----/\/\/\/\----50-ohm----
125w--> 100w 50w-->
<--25w <--50w

This explains everything at the average power level.
I suspect it also works at the instantaneous level.

> It is not obvious why you want to draw a distinction
> between elements that remove energy from a circuit by
> heating and those that do so in some other manner.
>
> Could you expand?

We are dealing with an ideal closed system. The
ultimate destination for 100% of the ideal source
power is heat dissipation in the two ideal resistors,
Rs and RL. What happens between the power being sourced
and the power being dissipated as heat is "of limited
utility".

> Is there some reason why you think that it is only
> necessary to account for the energy removed from the
> circuit by heating?

Heating is the only way that the energy can be removed
from the ideal closed system.

> And that you can ignore energy being removed in other ways?

No energy is removed in other ways. There is no other
way for energy to leave the ideal closed system.

> And how do you know the ideal source does not dispose
> of the energy it receives by getting warm?

An ideal source has zero source impedance, by definition.
All of the source impedance is contained in Rs, the
ideal source resistor.

> And the resistor, could it not also radiate some of
> the energy it receives? Perhaps even as visible light?
> Would that make it less of a resistor because it was
> not 'dissipating' the energy?

God could also suck up the energy or the universe
could end. Why muddy the waters with irrelevant
obfuscations? Please deal with the ideal boundary
conditions as presented.

> This is quite a leap.

Nope, it is simple physics through which you must
have been asleep.

> How would it violate conservation of energy if it was
> dissipated rather than going somewhere else?

It can only be dissipated in the resistances, by definition.
Nothing other than the resistances in an ideal closed system
dissipates power. EE102.

> In your model, what things could be done with the energy
> that would not violate conservation of energy?

FIVE TMES, I listed three things in previous postings. Since
you avoided reading it FIVE TIMES already, I'm just going to
point you to the "Optics" chapters on "Interference" and
"Superposition".

So I was generous in estimating 2.5 watts radiated
out of 100w input. In your case, it was more like
1 watt radiated out of 100w input.

Hi Jouko,

Basically, what you describe was discussed here last week as the W9INN dipole, and recently as the Lattin dipole. Being the same thing as your twin line (parallel line, or folded stub, or whatever); the premise is these elements resonate and thus trap an antenna for multiband operation. Those stubs are not oriented correctly.

Let's take this by degrees. Any dipole is a multiband antenna. Those bands might be useful, and they might not. The point is that being multiband is nothing remarkable in itself. What is remarkable is if that antenna is useful in every band you want to use it in. This is the "Holy Grail." Nearly 60 years ago, a Ham invented the Lattin antenna. We cannot say it was designed because it never performed according to claims (and I do mean NEVER). It was even patented.

Designs do work, inventions rarely do. We get inventors here every week, some hang around for years. The bottom line is that if these inventions worked, we would be using them (and that is 2% of the goal of these inventors, the other 98% is seeking validation as being eminent thinkers). The Lattin antenna's balance sheet shows 1PPM usage, and no pursuit of validation (the inventor is dead, but some still keep the vigil and change the flowers at Internet memorial sites).

You can try your hand at modeling by visiting:
http://www.eznec.com/
The Lattin design is easily constructed by a model, I've done several

dozen variations. You can also model stubs that are oriented
correctly and that will work.

Best way to build one of those is to reverse engineer one,

I don't see where there is any posting of his disigns either.

I suspect the traps are simple HiQ traps made from PVC and 14 Guage
Magnet wire.

Richard thanks for your answer and opinions.
I am not talking abt Lattin or W9INN.
These are things I hear in this thread for the first time.
I am talking abt using 1/4 wave stub as decoupling element
to make a (reduced size?) two band antenna.

This principle is used in commercial antennas like HY-GAIN AT-18
tower vertical and many others, stubs in line with element.
Orr in his antenna book is using orientation, open to center.but in line
with the element
So I am sure the principle works ok, and I was asking abt the different
orientation
alternatives. I understand that you would suggest 90 degree?
But does it really matter?

Designs do work, inventions rarely do. Yes I agree.
Therefore I am not going to build any complex mess where everything is
hanging of everything, just simple one time decoupling the element for
higher fequency.

Modeling real-world lossy stubs seems to violate
EZNEC's guidelines. How does one do it?

The series stub can be coiled in a circle
as a lot of commercial antennas do.

I see we need to back up a bit further.

Consider a 10 VDC ideal voltage source.

When 2 amps are flowing out of the positive terminal, the
ideal voltage source is delivering 20 joules per second
to the circuit.

Q1. Where does this energy come from?

When 1.5 amps is flowing into the positive terminal, the
ideal voltage source is absorbing 15 joules per second
from the circuit.

Q2. Where does this energy go?

Answer to both. We do not know and we do not care. An
ideal voltage source can deliver energy to a circuit
and it can remove energy from a circuit; that is part
of the definition of an ideal voltage source. It does
not matter how it does it.

But just as easily as it can supply energy, it can
remove it.

Without understanding these basics of the ideal voltage source, it will be impossible to correctly analyze circuits that include them.

Perhaps this has been the root cause of the misunderstandings.

...Keith

This WIKI article mentions the ability of an ideal voltage source to absorb power.

>But does it really matter?

Hi Jouko,

At right angles, yes. Does it matter? That depends on proximity to other conductors, including itself if you "coil" it around the radiator, or along the radiator.

When I looked at your first posting, I was confused by the single wire, and the text graphics should have been done in fixed font.

Keep the line conductors at least 3, preferably more, wire diameters from the radiator or themselves. Use the largest diameter for the multiplier of 3 (or more).

Hi Richard,

If you are talking about reverse engineering a lattin, that would be as satisfying as taking DNA samples from ghosts - it all hinges on finding one first.

There are enough examples on the Internet - too many, in fact, to say which is "authoritative." Doesn't matter as they are probably all equally incapable of meeting the general claim. Simply choose one, scale it from the bands it covers to those you want covered (yeah, easier said than done if it doesn't work in the first place).

Evidently line of sight means different things. I take it as the common used formula of the square root of the height in feet is equal to the miles to ground modified by about 1.2 to 1.4 for the way the radio waves bend around the earth.

Good stations using ssb and a couple of hundred watts can work close to 250 miles almost any time on 2 meters and 432 MHz. I have worked over 800 miles (North Carolina to Texas and the end of Florida) several times on 2 meters. Also close to that on 432.

Not sure how you want to calculate it, but have also worked England via a satellite that was out to around 22,000 miles.

I think I have a problem on the 28MHz band with the homebrew Cobwebb that I have made.

The SWR is 1.1 and is tuned at 28.500MHz.

If I listen to this band it receives strongest at 28.500 and drops off sharply after about 300KHz each side along with a rise in SWR It can reduce a S9 signal down to S1 on both sides.

Is this how the Cobwebb performs or is there some thing wrong with it?

I like to listen to a few people on 27MHz that I know. They are only 5 miles away. I have no problem hearing them on a G5RV but I can only just here them on the Cobwebb.

Many thanks

Jouko, I noticed this thread took a detour, but I never saw anyone
actually try to answer your question. I too, am looking to see the
answer on this.

It is amazing, all this talk about a Lattin antenna, that appears to
have lots of sites talking about how it works, but no one actually
having built one or used one, and a simple "yes" or "no" would answer
your question.

I don't have the answers or the means of testing one at this time. If
you get the answer direct, please post it here.

Thanks
Buck

Keith Dysart wrote:
> Q1. Where does this [source] energy come from?

An ideal source simply supplies a fixed voltage
devoid of any concern for efficiency or where
the energy comes from. This results in an
average steady-state number of joules being
supplied to the closed system per second.

> Q2. Where does this [reverse] energy go?

Once introduced into a closed system, it obeys
the laws of physics including the conservation
of energy/momentum principles and the principle
of superposition of forward and reverse
electromagnetic fields. You can use an ideal
directional wattmeter to track the forward and
reverse energy flows through the ideal source.

> Answer to both. We do not know and we do not care.

I have been telling you that your concepts violate
the conservation of energy principle and now you
have essentially admitted it.

> But just as easily as it can supply energy, it can
> remove it.

I'm afraid you will find that once the ideal source
has supplied the energy to a closed system, that energy
cannot be destroyed. If you are allowed to willy-nilly
suspend the conservation of energy principle, then any
magical event is possible and there is no valid reason
to even try to track the energy. It is one thing to
assume an introduction of steady-state power to a
closed system from an ideal source. It is another
thing entirely to allow destruction of that energy
once it has been introduced.

Hi Jouko

I thought Richard's statement that modeling would tell you about how the
design might perform, was good advice. If you use EZNEC, I'd be willing to
help you if you dont already know how to use it to model your antenna.

Roger Sparks wrote:
> This WIKI article mentions the ability of an ideal voltage source to absorb power.

It says: "A primary voltage source can supply (or absorb)
energy ..."

That's easy to comprehend for a battery source. Not so
easy for an ideal RF source with a zero series impedance.
If we define an RF source as a coherent RF battery, anything
is possible (at least in our minds). Which of the following
makes more sense?

1. Destructive interference energy is stored somewhere
in the system and delivered back to the system 90 degrees
later in the cycle just as it is by a physical inductor
or capacitor.

2. An RF battery inside the ideal source stores the extra energy
in coherent RF form and delivers it back to the system as needed.

> http://en.wikipedia.org/wiki/Voltage_source

It also says: "The internal resistance of an ideal voltage
source is zero;" So exactly how does something with an
internal resistance of zero absorb any power?

Hi Jouko,

At right angles, yes. Does it matter? That depends on proximity to
other conductors, including itself if you "coil" it around the
radiator, or along the radiator.

When I looked at your first posting, I was confused by the single
wire, and the text graphics should have been done in fixed font.

Keep the line conductors at least 3, preferably more, wire diameters
from the radiator or themselves. Use the largest diameter for the
multiplier of 3 (or more).

Hi Barrett,

1. You either copy an existing design and follow their specifications
for this explicitly;

2. You model the design and plan to trim length, and/or adjust turns;

3. You throw something together and (again) plan to trim length,
and/or adjust turns.

The placement of the coil along the radiator by actual distance and
proportion, seriously changes its requirements for any application.
That is to say, a 50 turn coil, with turns every 3mm, and a 4cm
diameter will work for one frequency at one position for one length of
wire ONLY. And even height above ground may upset this too; but
perhaps not as much as the first set of variables.

Hi Barrett,

SWR change within that small a portion of frequency should not affect
receive to the degree you describe.

>Is this how the Cobwebb performs or is there some thing wrong with it?

Is it pointed in the right direction? Can you manually tune it?

Jerry, thanks for the offert.
I dont know how good these modelling programs are in this situation.
But if it is easy, so could somebody do the following:

Take 20m of wire, that is half of a dipole.
Put a 1/4 electric wavelength shorted stub for 10,1MHz so that the open end is 7,25m from center and the shorted end pointing to the tip of antenna. One side of stub is the 20m wire itself, like in the upper picture. Ignore all velocity factors to make it sinple.
Now tell me what are the resonance frequencies of that kind of element and if possible feed point impedande (80m and 30m)

I know I could do it myself but as you know learning to use a new program reliably takes lot of time.

That's true for an ideal 1/2WL stub but for an
ideal 1/4WL stub, an open at the far end will
appear as a short at the feed end and a short
at the far end will appear as an open at the
feed end.

Hi Jouko

I am not sure I am reading your text properly. But, I did model a 40
meter wire with a trap on each side. You are welcome to E-mail me if you
want to see what EZNEC says about *my* model. Maybe you can help me model
your concept.
I have a friend in vasa Finland who can get you any information about
contacting me. Google Patrik Tast.

I did just that with EZNEC, but with a free-space dipole. Without the
stubs, the antenna resonated at 3.6 MHz. With the stubs, that dropped
to 2.75 MHz and additional low-impedance points were noted at 6.5 and
11 MHz. The patterns at 2.75 and 6.5 had the desired dipole shape,
but the 11 MHz pattern had multiple lobes.

You have it just backwards. A 1/4 wave stub is an impedance converter. i.e.
a short at one end appears as an open at the other end.

Your original question:
>>>My question:
>>>Is there any difference if the shorted end is pointing to the center or to
>>>the tip of dipole.
My specific response:
Keep the line conductors at least 3, preferably more, wire diameters
from the radiator or themselves.

Certainly more was said, but you have shied from terse responses in
the past.

You have a tuned line, that is illustrated several times by you. You
have a radiator, that is illustrated several times by you. You have
asked about the line in proximity to the radiator several times, that
is illustrated several times by you (you really need to use fixed font
to do this, it is the protocol of allowing everyone to see what you
mean). I have responded about the proximity of the line to the
radiator several times with a very simple rule.

The line going radially away from the radiator (at right angle)
absolutely satisfies that rule. Keeping the line away from the
radiator (at a 0 degree angle, either up or down towards a tip) can
also satisfy that rule - but only if you observe the rule. If you do
not observe the rule you will have problems. You may have problems
even if you do - but your question lacks your requirements.

So, ostensibly, yes there is a difference - this is just the nature of
life. The real question is would it matter to you? Some folks worry
over half a dB, others can live with -10dB. This has all been
discussed to some length by others, in related topics about hairpin
matches. A general reading of the postings helps put specific
problems into context and relationship. This means browse the topics

that are active - not just your own.

Now, do you have an original question that has gone without an answer?

Unless we allow it absorb energy with the same ease that it emits energy.

No, the problem here is that the individual switched batteries that would make up this system would not be equally discharged. Some would actually gain charge, and never deliver power to the system. So I don't like this choice.

> 2. An RF battery inside the ideal source stores the extra energy
> in coherent RF form and delivers it back to the system as needed.
>
This sounds identical to the 1st choice. You can make such a circuit with many individually switched batteries so it becomes a good test of the theory. Again, some of the batteries would actually gain energy.

> > http://en.wikipedia.org/wiki/Voltage_source
>
> It also says: "The internal resistance of an ideal voltage
> source is zero;" So exactly how does something with an
> internal resistance of zero absorb any power?

How do we deal with the I x E power when the reflected voltage is greater than the forward voltage from the source? One way is to ignore it and only deal with averages. Another is to allow the ideal voltage source to absorb power. A third way is to allow the energy to be stored in constructive and destructive interference some place in the system. A fourth way is to allow reflections from the ideal voltage source with the result that power will build internally and the phase shift of the resultant system wave will shift farther away from

the driving voltage, until some stable power input to disipation rate is reached.

I like your RF battery idea. It could actually be built to a close approximation of an actual sine wave.

How can a device with a zero impedance, i.e. zero resistance,
zero capacitance, and zero inductance, absorb energy? We can
certainly allow it to magically absorb energy but of what
use is that?

> A third way is to allow the energy to be stored in constructive
> and destructive interference some place in the system.

As you know, this is the one I prefer. Another thing that
neither you nor Keith has done is to account for the
reverse-flowing energy through the source. I suspect if
that was done, every thimbleful of energy would be
accounted for. So far, net energy calculations have been
used on one side of Rs and component energy calculations
on the other. That would work only if Rs was not dissipating
power.

Hi Barrett,

That is line of sight, easily. As you suspect, you should hear your
friends. Your turning it is OK. Your SWR readings would suggest your
line is OK, your antenna is OK. Aside from using a manual tuner (you
say nothing to my question there), that leaves the receiver as being
suspect.

Great minds think alike. :-) I was doing the same thing
at different frequencies. I noticed that a 1/2WL dipole
with 1/4WL stubs on each end tends to resonate on frequencies
in a ratio of about 2.57:1. 18.14/2.57=7.06 so such an
antenna should be resonant on both 17m and 40m. EZNEC
agrees. Here are the approximate dimensions for the dualband
40m/17m antenna. Cutting and trying will be necessary for
fine tuning to resonance. Note that the antenna is about 13
feet shorter than a 1/2WL dipole on 40m. It has a dipole
pattern on both 40m and 17m and a 50 ohm SWR less than 2:1
on both bands. It appears to be linear-loaded on 40m and
stub-matched on 17m.

```
26.8' 26.8'
+-------------------------FP-------------------------+
| |
+------------ ------------+
13.3' 13.3'
```

Since 10.125/2.57=3.9 MHz, this antenna should be scalable
to become a dualbander on 75m and 30m.

Hi Jouko,

If we are looking at four wire segments to the left of the center of the dipole, then this is a lattin design element. All my comments about that stand.

As for speculating where it resonates, there is not enough dimensioning to be exact (while there is little enough to make a poor guess).

I would only ask, do you want it to act as a trap such that the radiating portion of the antenna is confined to the right (as illustrated in your link) of this construction (like a conventional trap for a dual band operation)? Or do you want the element to act as linear loading to make the entire structure resonate at a shorter physical length?

If you turn the element, yes, it will make a difference. There is still a long road to travel to make it "work" and it probably won't look like your link's illustration and it won't resonate where you expect it to.

You still have to observe the separation of the two lines by at least 3 times the largest diameter wire/rod.

Hi Jouko

I suspect that you either understimate your ability to learn or you arent aware of how EZNEC works. I submit to you that a modeling program is the best method of establishing the antenna design you are describing. You can probably learn everything you need to know about your antenna within a few hours of thinking on your own. You dont need to attend a class room course on use of the EZNEC program.
I considered computer modeling to be beyond my ability till Richard Clark encouraged me to 'just try it'. I tried it, and I consider the program to be the best tool a HAM could have for developing antennas. I am sure you will figure out how to model your "trap" antenna and learn how well it will work for you within a very short time. You even have access to some EZNEC experts from this rraa group. Try it, you'll like it.

Hi Richard

I have a manual tuner and two auto tuners that I have used and it makes no difference to improve the received signal. I have also used two different radios with the same outcome.
I'm wondering if the G5RV is to close and is causing this or if the square 10"x10" mounting plat that I have used in the centre of the Cobwebb might be causing the problem.

The G5RV is at the same height as the homebrew Cobwebb and they are about 15ft apart. All other bands do not sharply drop off like 28MHz does on receive signals.

Thanks

Hi Barrett,

One other thing that comes to mind is you may be cross-polarized,
which for line of sight transmission (and this close proximity so
qualifies) can exhibit substantially depressed signals.

This would mean that your Cobwebb homebrew is very much horizontally
polarized, and that your G5RV has enough slope to it to be
sufficiently vertical to your buddie's vertical signals.

I will let you sort out the particulars - like the buddies are also
vertical (if not, well, there goes that theory).....

10.2/3.6=2.8 It appears that frequency ratios
between about 2.4 and 2.8 can be easily achieved.
That's 75m+30m, 40m+17m, 30m+12m.

Unfortunately, a 2:1 ratio seems difficult to
achieve.

>
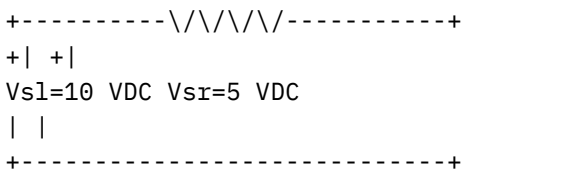
> > Q2. Where does this [reverse] energy go?

You have morphed the questions. Let us try again.

Try two ideal voltage sources arranged in the
circuit below.



Using the circuit analysis technique of your
choice you should find that 1 amp is flowing
through the resistor.

The ideal voltage source on the left is providing
10 joules/second to the circuit.

Q1. Where does this energy come from?

The ideal voltage source on the right is absorbing
5 joules/second from the circuit.

Q2. Where does this energy go?

Answer to both. We do not know and we do not care. An
ideal voltage source can deliver energy to a circuit
and it can remove energy from a circuit; that is part
of the definition of an ideal voltage source. It does
not matter how it does it.

But just as easily as it can supply energy, it can
remove it.

Without understanding these basics of the ideal voltage source, it will be impossible to correctly analyze circuits that include them.

This has been the root cause of the misunderstandings.

> later in the cycle just as it is by a physical inductor
> or capacitor.
>
> 2. An RF battery inside the ideal source stores the extra energy
> in coherent RF form and delivers it back to the system as needed.

3. An ideal source provides or absorbs energy to satisfy its
basic function which is to hold the voltage across its terminals
at the desired value. When it is providing energy we do not know
where this energy comes from and when it is absorbing energy we
do not know where this energy goes.

> >http://en.wikipedia.org/wiki/Voltage_source
>
> It also says: "The internal resistance of an ideal voltage
> source is zero;" So exactly how does something with an
> internal resistance of zero absorb any power?

Unknown. Just as we do not know where the energy that an ideal
voltage source sometimes provides comes from.

But you are invited to speculate on the many ways that it might
be done. Just as you might speculate on where the ideal voltage
source gets its energy when it is providing energy to the
circuit.

Just as there are real devices which approximate ideal voltage
sources delivering energy to a circuit (commonly called power
supplies), there are devices which approximate ideal voltage

sources that remove energy from a circuit. Check the Agilent catalog for "DC Loads". Perhaps the schematic will provide what you seek. Of course power supplies and DC loads are typically one quadrant devices, but with a little ingenuity you can combine them to form a two quadrant device which would be an even better approximation to an ideal voltage source.

Hi Richard

You might have the answer there. I will ask my friends tomorrow what Ariel's there using. The G5RV is a homebrew half size with 300ohm vertical feeder straight into 50ohm coax that has a coax Air Core Choke Ugly Balun in it.

Thanks

I don't recall the type or service but those radios that run less than 1 watt and sell for about $ 29.95 a pair must be the ones you are talking about. I know a couple of hams that have exceeded that distance by a whole lot. One of the hams was on top of Mt. Mitchell (highest point on the east coast).

An intriguing response.

It was such a good example that it just stopped you in
your tracks.

But was this because you have learned that you were in error
and now better understand the behaviour of sources when
they are absorbing energy?

Or was it because you have realized the contradictions
inherent in your previous explanations but can not
work out how to resolve them?

Or was it because you have detected just a hint of the
contradictions to come and want to give up before having
to realize their full impact?

This discussion about ideal sources and power absorption would be rather amazing if I hadn't seen so much of the long sad history of this whole thread. It's just another diversion to deflect the discussion away from some of the sticky problems with alternative theories.

It looks like Cecil could benefit from momentarily abandoning his power waves, virtual reflections, photons, s parameters, and constructive interference, and go back to basic first or second semester electric circuit theory. Connect an ideal voltage source to a series RL or RC -- all elements lumped, not distributed. Find the power P(t) at each of the three nodes. (It's easy. Just calculate v(t) and i(t) and multiply the two.) Remember that the sign of P(t) shows the direction of energy flow. If I had the patience and self-control to participate in this endless thread (and I admittedly have neither), I'd refuse to say another word about it until Cecil shows that he knows what the power waveforms are at those three nodes. Why argue with someone about distributed networks who hasn't mastered lumped circuit analysis?

Correction: Finding the voltage requires a reference node. So the power needs to be found at only two of the nodes, with the third being the reference (ground) node.

In real life, at least in my case the stub will be made of twin-lead type material which shortens it abt 30%.
If the shortening effect at lower frequency due to the inductive loading of stub is less, then it would be possible.
Going one step further you could easily add another band to the design as parallell dipole for 17m using unused parts of
douple-line. That should have litle interaction to the original double band antenna.
http://farm4.static.flickr.com/3016/2420028687_e9fd3b1e6c_o.jpg

As Jim K7JEB verified, the total half length is not 20m but 15,5m due to the loading effect of the stub.
The real stub length is 1/4 WL at higher frequency respecting the velocity factor of material used.

Hello, all, and then there's that circuit topology problem found in some circuit theory textbooks:

There is an infinite planar square lattice of connected 1-ohm resistors that extends to infinity in all directions. A DC ohmmeter placed across any resistor would register what value? The answer is 0.5 ohm but how do you go about solving for it? (Hint: There is an easy way and a much more difficult (general) way to attack this problem. This problem is a discrete example that in the limit would indicate the distribution of a DC electric field (and currents) in a conducting, isotropic metal plate as one moves away from the source of excitation. Sincerely, and 73s from N4GGO,

Source record: 25983

Are there any companies that sell the big-ass glass/ceramic antenna strain and standoff insulators anymore?

Most of the ham antenna places that sell wire antennas have a single style of really tiny ceramic strain insulator, and one or two plastic strain insulators, but they all obviously are made by the same company and imported. Nothing wrong with them, but the ceramic one really will not hold any rope above 3/16", and the plastic one won't take any rope above 1/4" (and even that only with some effort.)

I have been buying good insulating plastics (e.g. G-10, Polycarbonate, etc.) and making my own insulators, but if there were a good source of the big classic ceramic and/or glass ribbed insulators - not just strain but also the standoffs - I'd buy them in a hearbeat.

Cool old insulators do show up on E-bay etc. but they're generally onesies-twosies and obviously being sold to collectors, not hams who string them up on antennas.

I can go to the industrial supplier indices and find companies, even local companies, that custom-make ceramic and glass insulators for the electrical industries, but they have no intention, or even mechanism if I call them, of selling a dozen insulators to an individual ham. If anyone knows of an exception, please let me know!

Not at all. Everything I have said applies to a
distributed network. Since you insist on using a
lumped circuit source in a distributed network
example, further discussion is futile because
you are mixing apples and oranges.

What you perceive as the source absorbing energy is
the reverse traveling wave energy flowing back through
the source unimpeded. After all, how much energy can
be absorbed by 0+j0 ohms? The illusion of energy
absorption is the direct result of you refusing to
deal with the component wave energies.

Roy, after your use of standing-wave current with
its unchanging reference phase (as reported by EZNEC)
to measure the delay through a 75m bugcatcher coil
as virtually zero delay, it is obvious that your
"lumped circuit analysis" cannot be trusted. Want
to read about "... the Failure of Lumped-Element
Circuit Theory" and diagnose your errors regarding
those loading coil measurements?

It gives a tool to check our work inside the system. We think we know what happens once the energy arrives into the known components, but we don't know what exactly happens in the voltage source itself. We solve that by equating "energy in equals energy out". Then we refine that equation to "energy in equals energy returned plus energy disipated plus energy stored during some time period". Ein = Er + Ed + Es

This is the "conservation of energy" principle at work.

> > A third way is to allow the energy to be stored in constructive
> > and destructive interference some place in the system.
>
"A third way is to allow the energy to be stored in constructive
and destructive interference SOME PLACE IN THE SYSTEM." In this quote, I capitalized "SOME PLACE IN THE SYSTEM" because we need to understand where interference is located. If interference is located within the voltage source, it is really located *OUTSIDE* the system because we do not completely understand the voltage source itself.

Are you expecting additional reflections? Any additonal reflections from the source would only be mechanical copies of the reflection at the short, and would add or subtract to the forward wave following the rules of sine wave addition.

But how can we have a source with zero resistance, zero capacitance, and zero inductance because in the real world, any source has impedance? The short has "zero resistance, zero capacitance, and zero inductance but it does not emit energy nor have a reverese voltage, both properties of the voltage source. It is not reasonable to assign the properties of the short to the voltage source, ignoring the reverse voltage situation, and expect reflectons from the source to be identical to reflections from a short.

There's a miscelaneous collection here:

http://www.surplussales.com/antennas/AntennaSubIndex.html

Since it's "surplus", I don't know how repeatable their selection is.

Actually, all we need to realize is that, in a
distributed network, the current through the source
is NOT equal to the current being provided by the
source. It is the source current superposed with
reflected current and re-reflected current. The fact
that the *NET* power is negative is NOT because the
source is sinking power. It is caused by the other
"sources" of energy in the system, i.e. the energy
in the reflected waves.

> Are you expecting additional reflections?

Once steady-state is reached, the magnitude of the
reflections are also steady-state. The total energy
flowing toward the load is the forward energy. The
total energy flowing in the other direction is the
reflected energy. Both of those magnitudes are fixed
during steady-state.

I have asked multiple times that this simple mental
experiment be performed and my request has been ignored.

Please install an ideal 50 ohm directional wattmeter
at point 'x' and tell us what are those readings
for forward power and reflected power.

GND--Vs--x--Rs--------45deg 50 ohm----short
100v 50ohm

Once the forward and reverse energy flows at point
'x' are understood, it will become clear that all
of the net current through the source is NOT being
provided by the source. That the source is sinking
energy is an illusion caused by reflections.

I have a stainless steal 1/4 wave length mobile whip.

Can I mount this on top of a 20ft aluminium scaffold pole and use the pole as the ground radial?
I also have a mobile AM-80 for 80 meters. Can I mount this in the same way and will it work ok?

Thanks

Hi Barrett,

The combination will give you an offcenter, vertical dipole (for
either band you are investigating).

This is not a bad thing, just something that may not tune up the way
you think it "should."

The 10M application will have three sections:
1. The quarterwave whip;
2. a 5/8ths wave lower section (the pole);
3. an undefined length of transmission line (unless you choke it).

Source record: 26008

Hi folks,

I thought many of you might be interested in seeing this:
A recently updated database of 72(!) Windom (actually CL-OCFD)
radiation patterns for different antenna heights:

http://hamwaves.com/cl-ocfd/patterns.html

(Takes a moment to complete loading.)

It gives one a grip of how antenna height influences take-off angles
on different bands. Also, the basic shape of the radiation patterns is
very instructive about how Windom antenna behave in general.

I hope you enjoy!
All comments invited.

> and one at 10.2 MHz.

I also played around with this yesterday on EZNEC. Started with a 75 M center fed half wave at 30 feet high, added 20 M quarter wave stubs one quarter wave (20 M) oout from the center. Got two low SWR points at ~3.5 MHz and ~14 MHz. By changing the distances to the stubs, the length of the stubs, and the length beyond the stubs, I got the low SWR points to 3.9MHz (2.8:1) and 14.2 MHz (1.2:1). Azimuth pattern on 14.2 MHz was sort of omni-directional with major lobes at 45, 135, 225, and 315 degrees. Pattern on 75 M was omnidirectional at high angles and max gain straight up.

Conclusions: Might be useful as a way to add 20 Meters to a shortened 75 M dipole. High SWR on 75 would still require a tuner. Losses were not determined. More height might help.

Ken Fowler, KO6NO

Yes, in nature the returning power will affect the frequency of the source. The ideal voltage source absorbs the reflected power rather than allowing a change in frequency.

This circuit has an impedance of 73.5 + J44.1 ohms at the point x. Energy sinking into the source occurs during the cycle. It is not an illusion.

Think of things this way. Any signal must contain energy. A signal without energy is not a signal. Nature must have some method of signaling between source and load when the load does not match the impedance of power flow. This is simple logic based on the known fact that the apparent impedance of a transmission line depends upon the load at the end of the transmission line.

Power returning to the source is the signal nature requires to throttle the output of the source. Power returning to the source will change the frequency of the source in nature, but in our ideal voltage source, nature is suspended and the frequency is held constant. Our problem as engineers is to isolate each effect and to make valid predictions so that we can build more intelligently.

That's a conventional trapped dipole with stub traps
instead of LC traps. Here's a graphic from my web page:

If the reflected wave is a sine wave coherent with
the forward wave, why would the frequency change
when they are superposed?

>> GND--Vs--x--Rs--------45deg 50 ohm----short
>> 100v 50ohm
>>
> This circuit has an impedance of 73.5 + J44.1 ohms
> at the point x. Energy sinking into the source occurs
> during the cycle. It is not an illusion.

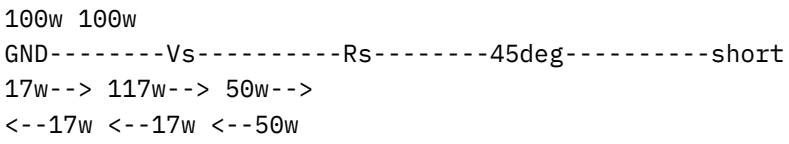
I got a different impedance value but for purposes
of discussion, all that matters is that the impedance
is NOT 50 ohms.

Let's assume your impedance is correct. That means
the ratio of reflected power to forward power at
point 'x' is 0.1452 in the 50 ohm environment.
Why would reflected energy flowing back through
the source be considered "energy sinking". Why
cannot the reflected energy flow back through the
source unimpeded by the 0+j0 impedance and be
reflected by the short to ground on the other side?
That same thing happens all the time to standing
wave current on the outside of the coax braid.
Why do the laws of physics change inside a source?

In this example, we are delivering 100 watts to Rs.
With a power reflection coefficient of 0.1452, the
forward power has to be 117 watts making the reflected
power equal to 17 watts at point 'x'. That reflected
power of 17 watts is not absorbed by the source. It
flows back through the source, unimpeded by the 0+j0
impedance, and is reflected by the short to ground.
It joins the 100 watts being generated by the source
to become the forward wave of 117 watts. No absorbing
of energy required - just good old distributed network
physics.

Once this 17 watt wave is tracked back through the
source, reflected, and superposed with the 100 watts
being generated by the source, all will become clear

without any power absorption by the source being
necessary. Here's a diagram of what's happening.



All energy flows balance perfectly and there is no
absorption by the source.

Depends on whether the patio is conductive or not.
Probably best to rest the base on an insulator.
Also be aware that, at 100 watts, there will be
hundreds, if not thousands of volts present at
the base of the pole. I once keyed down while
a cat was standing on one of my radials. Not
sure where it went, but it might have gone
into orbit. Have you considered sleeving the
pole inside PVC pipe for safety reasons?

Hi Barrett,

Not something I would worry about. Others may, and they will
certainly chime in if they do. I had a 10M vertical off-center dipole
mounted about 1 foot above ground and it seemed to work fine; but not
as well as my buddies with higher antennas. My guess is that an 80M
version may suffer more. I fed the transmission line up through the
bottom section.

A glass jar (eg a jam jar) makes an effective insulator for the base of
a pole. Or a polythene bucket!

In the past I've purchased ceramics from Surplus Sales of Nebraska,
and they're still on the web site. Go to the alphabetical index and
look under "I" for insulator -- prices range from 98 cents to $795,
depending on how "big-ass" you want to go :-)

4336. 20m whip on 30m?

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-17 20:59:24 UTC
From: kuzen001@duke.edu
Message-ID: <fu8dnc$s8v$1@gargoyle.oit.duke.edu>
Source record: 26007

I'm in a tiny apartment for a while and plan to put a Hamstick-style whip on a mount clamped to a windowframe, to see if I can work a little PSK31.

I wanted a HF whip for 30m but couldn't easily find one. I bought whips for 20 and 40. They're the usual things--5' fiberglass rod, 3/8-24 fittings at each end, loading wound onto the fiberglass rod, with a flexible whip at the end, adjustable in length, for tuning.

I'm wondering about making an extension for the base--a length of aluminum or something, with 3/8-24 fittings at each end, and trying to get the 20meter whip's resonance down close to 30meters. Anybody tried this, have any advice/suggestion/information? TIA!

It would take much less length if you extended the stinger vs
extending
the base below the windings. It will take a lot of mast to tune it to
30m
if you keep the same stinger length. I'm talking in feet, not inches.
But you can extend the stinger just a few inches and tune it to 30m.
You will need to find a longer stinger if that one won't extend out
enough, and it probably won't unless there is plenty left after
tuning it for 20m. For maximum efficiency, extend both ends.

Look for the insulators used in tower guying systems.

4340. G5RV Half size

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-17 23:24:58 UTC
From: Barrett <barrett@blueyounder.co.uk>
Message-ID: <f%QNj.94969$qj3.27626@newsfe20.ams2>
Source record: 26012

If I join some extra wire to the ends of the G5RV half size and bring them down towards the bottom of the 300 Ohm slotted feeder to make a triangle shape, kept vertical. Would this radiate ok or would it be a waist of time?

Is there a modelling program I could buy for HF antennas?

Thanks

> you are mixing apples and oranges.

So you are saying that ideal voltage sources work differently
in distributed networks than they do in lumped circuits.

Perhaps you could expand on the differences using the
following two circuits. This one is lumped.

```
50 ohms
+----------\/\/\/\/-----------+
+| +|
Vsl=100 VDC Vsr=50 VDC
| |
+-----------------------------+
```

And this one is similar but includes a transmission line.

```
50 ohms
+----------\/\/\/\/----+----------------+-------+
+| arbitrary +|
Vsl=100 VDC length, any Vsr=50 VDC
| impedance line |
+---------------------+----------------+-------+
```

After the circuit has settled how will the ideal voltage
sources on the right be behaving differently in the two
examples? If you think it matters, try 50 ohm line.

Where does the energy being absorbed by these ideal voltage
sources go?

> What you perceive as the source absorbing energy is
> the reverse traveling wave energy flowing back through
> the source unimpeded. After all, how much energy can
> be absorbed by 0+j0 ohms?

None. But pushing a current against a voltage (regardless of
the cause of the voltage) will definitely use energy.

> The illusion of energy
> absorption is the direct result of you refusing to
> deal with the component wave energies.

These circuits are DC, but Vf and Vr still work. The line settles to a constant (over length) 50 V regardless of the line impedance, but the value of Vf and Vr will depend on the impedance of the line. Why does it settle to 50 V? What else can it do? It is connected to a 50 VDC ideal voltage source.

Using a line impedance of 50 ohms, compute Vr. Ooopppps. Vr is equal to 0: no reflected power.

The ideal voltage source on the right, after the circuits settle, will be absorbing 50 joules/s in both cases.

4342. Ground conductivity's effect on vertical

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-18 04:56:01 UTC
From: Al Lorona <al_lorona@agilent.com>
Message-ID: <IQVNj.8690$V14.7742@nlpi070.nbdc.sbc.com>
Source record: 26014

Hi, Everybody,

In the process of modeling a vertical antenna (specifically, I am using EZNEC 5.0) I am noticing an effect I did not expect which could be the result of a modeling error on my part.

The antenna is a 34-foot vertical above (12) 34-foot radials, making it a 1/4 wave on 40 and a 1/2 wave on 20.

On 40, the antenna works as I expected; as the ground conductivity goes up, the gain and efficiency of the antenna both increase, too.

But on 20, if I increase the ground conductivity from, say, 0.005 to 0.008 S/m, the max gain and efficiency *decrease*! This is counter-intuitive to me.

Can anyone point to something I'm doing wrong?

Thanks,

Al W6LX

None of the ideal components we use for linear circuit analysis exist in the real world. We use ideal resistances which have no inductance or capacitance, capacitances which have no resistance or inductance, ideal inductances which have no resistance or capacitance, ideal controlled sources which operate over an infinite range of control and output values. And try making anything even vaguely resembling an ideal transformer. So what's the problem in accepting an ideal voltage source as another model element? If you want a better approximation of something you can build in the real world, add an ideal resistance to the ideal voltage source, and you'll have a much better representation of most real sources.

As for the way the source reacts to an impinging wave, note that the voltage across a short circuit doesn't change when a wave hits it. Neither does the voltage across an ideal voltage source. Consequently, they do have exactly the same effect on waves.

Ground loss is a sort of impedance matching problem. If you have perfectly conducting ground, there is no ground loss. If you have perfectly insulating ground, there is no ground loss. There's always some ground conductivity in between those extremes at which the loss is maximum. This value depends on the frequency among other things. Try a wider range of conductivities and you'll find this point.

You should also be aware that if you have radials which are above but close to the ground, half wavelength ones can be considerably less efficient than quarter wavelength ones. One reason is that the points of maximum current are out near the centers of the radials, where they induce current into the lossy ground. When the radials are a quarter wavelength or shorter, the current maxima are near the center, so their fields nearly cancel. Another often-overlooked fact is that radials very close to the ground are electrically considerably longer than when more elevated. So radials which are a quarter wavelength in free space can have their current maxima well out from the center which results in lower efficiency.

I only have EZNEC 3 and the EZNEC 4 demo.

I don't remember the dimensions, but I remember that in the
instructions, EZNEC could not make accurate measurements with parallel
wires within a certain distance like 8-10 inches.

(someone correct me here.)

holding that assumption...

I have not modeled that antenna or made one, but I had an experience
with an 80 meter dipole that may relate. I cut a wire way too long
for 80 meters, I think it was something like 140 feet or so. I use
insulated stranded copper wire so I tried folding back the ends until
I shortened the antenna to 75 meters. What I discovered was, that the
change in frequency of the antenna did not match the reduced length of
the wire. After trying for quite some time, even after measuring the
antenna, I found it physically shorter than the calculated length, but
the center frequency, which changed a little, hadn't changed
significantly as expected. My conclusion was that I basically made a
linear-loaded dipole and the total electrical length of the antenna
was basically the wire length minus a small amount for interaction
between the folded back wire and the original leg. It wasn't until I
trimmed the wire itself that I raised the frequency of the antenna.

The wire I used had the ends loosely wrapped around the main wire of
the dipole, not tightly wrapped like the turns on a hangman's noose.

It was insulated THHN stranded copper.

Let's look at the 40/80 meter antenna cut for the CW portions (3.5 & 7 MHz). Assume, for the sake of argument that the 468/f = length in feet accounts for the velocity factor and that it is the same for the 40 meter portion as the whole wire...

In theory, the Lattin antenna should be a total of 133.7 feet long, with 66.85 (1/2) of the total length being the 40 meter wire and 1/2 on each end being the 40 meter decoupling trap. Overall there is a total length of 200 feet of wire which theoretically would give you 40 and 80 meters. UNLESS the RF reacts according to my experience above which would produce an antenna which would be tuned for 7.0 and 2.3 MHz (give or take reaction)

If this is true, and even with the reaction, the 40 meter dipole would work, but you couldn't make the Lattin antenna work with the those two bands. I might assume that 30 and 80 meters would work as the total length of the 30 meter portion with trap would be less than 133 feet and the 80 meter dipole would extend past the trap as an additional extension of wire. Presumeably, that antenna would be resonant on 30 meters, 80 meters and somewhere else, maybe close to 6 or 7 mhz (Total length of the wire from feed to end of trap.)

I don't know how the diagram shows, I hope you get an understanding of what I am saying.

Comments?

==========

PS, after writing all that, I re-read your post more carefully. I think your EZNEC model reflected what i said all along. The difference being that the continuation of the 80 meter dipole element seems to be overlooked by EZNEC.

(ok, done this time :)

Thanks to everybody for valuable comments.
Special thanks to Jim K7JEB, who made the simulation and verified that the
antenna
works as expected.

After much confusion with the text graphics, I learned the lesson to never
use them again

So here is how the antenna works
http://farm4.static.flickr.com/3078/2423002784_8c7c03acc4_o.jpg

I am going to use this kind of material, which is very commonly used by
telephone companies here.
http://www.saunalahti.fi/hohtola/ham/killu/killu.html

And here is how it will be made:

http://farm3.static.flickr.com/2072/2422189823_285653e9b9_o.jpg

Why not normal traps? Easier to build
Why not parallell dipoles? Much shorter
You get three bands if needed very easily

I think its called a modelling program? I was told a long time ago that's there is a program where you can input the shape and size of an antenna and it will predict how well it would work.

Is there such a program and how simple is it to use?

At the moment I'm trying all different setups to try and get the best I can, because of the space and the neighbours.

Many thanks

Cecil, got a question for you.
I have another 20ft pole mounted on the back of my house and it is rested on the patio floor. I plane to put up a Cushcraft MA5B on this pole and a 2/70 collinear on top. Does this mean that there will be high voltage on the pole beneath the beam from the beam or from the collinear?

The children will be out in the garden when the weather gets better.

Thanks

> Roy Lewallen, W7EL

Perhaps it would help clarify the thinking to plot some voltage-
current
curves.

If we plot V versus I for a resistor (with V on the vertical access)
we
get a line with a slope equal to R. This line passes through the
origin.

For a short, the line is horizontal (i.e. slope and R are zero) and
for
an open the line is vertical (i.e. slope and R are infinite).

Now plot the V-I characteristic of a resistor in series with an ideal
voltage source. Again it is a line with a slope equal to R, but it

does
not pass through the origin, it crosses the vertical axis at the
voltage
provided by the source. So the y-axis crossing is controlled by the
voltage source and the slope is controlled by the resistor. If you
reduce the resistor to zero, you get a horizontal line crossing
the y-axis at the voltage of the source. The line being horizontal
means that no amount of current will change the voltage.

We often talk of resistance as V/I, but there are many situations in
which it is better to think of it as deltaV/deltaI (or, in the limit,
dV/dI); that is, the change in voltage that accompanies a change
in current. This is exactly the slope of the V/I curve at that point
and works for computing resistance regardless of whether there is a
voltage offset present.

And this is how the source resistance of a battery or power supply
would be measured. Measure the voltage and current at one load,
change the load, measure the new voltage and current, compute the
source resistance from the changes in the voltage and current.

This dV/dI view of resistance is extremely useful and can be
applied to devices with very complex V-I curves. Consider a
tunnel diode (http://en.wikipedia.org/wiki/Tunnel_diode).
Over part of its V-I curve, the slope (i.e. resistance) is
negative. If we put a tunnel diode in a circuit with appropriate
bias such that the tunnel diode only operates over this range
of its V-I curve, then for the purposes of that circuit it
can be modelled as a resistor with negative resistance.

Think R=dV/dI, not R=V/I.

...Keith

I grant that the case for true frequency change was overstated. There is a one time phase change, causing a frequency "bump" for one cycle. This phase change is a one time event, occuring for each successive and diminishing reflected wave.

It is the arbitrariness that I object to. As you say, you chose 50 ohms to calculate the reflection factor. So we have a 50 ohm transmission line zero length long, reflecting from a short circuit. This does nothing for us. We still have the source absorbing power, but

now we have now added a mechanism for how the absorbed power behaves within the source.

I think we have had a discussion about this previously. I can see that within this thread we have at least three expectations of what happens within the source when a reflection arrives; absorbed, controled reflection, and acts like a short. Vigourus arguments are presented for each expectation, but who can measure what happens within an imaginary device? The seed for an endless argument!

There are a couple programs out there that are free for use. The demo program of EZ-nec, and 4Nec2.

What I would suggest is getting a copy of EZNEC. Then go through the tutorials.

As for easy or difficult, you sound like a real new guy - that's okay, no one was born knowing all this stuff, and we all have to start somewhere. The important thing is to start. It will probably be a little daunting for a while.

How familiar are you with the basic concepts? Then we'll know where to start. There are some good web references out there, depending on where you want to start.

The 300 ohm line is a series-section transformer that
works with the G5RVjr antenna feedpoint impedances
encountered on 40m, 20m, 10m, and 6m. If you change
the antenna, you change the antenna feedpoint impedance.
It would be a virtually impossible coincidence if the
same series-matching transformer worked well on a
different antenna.

> Is there a modelling program I could buy for HF antennas?

EZNEC is available from www.eznec.com. Before buying,
you can test drive the free demo version which has
a 20 segment limit. EZNEC is a very time efficient
way to learn about antennas.

Keith Dysart wrote:
> So you are saying that ideal voltage sources work differently
> in distributed networks than they do in lumped circuits.

"Work differently" is a loaded expression. Since both
lumped circuit and distributed network models exist,
it is safe to say that the lumped circuit model and
the distributed network model indeed "work differently".
If they didn't "work differently", there would be no
need for both of them to exist.

Your previous error is obvious. You were using the
lumped circuit model on the left side of Rs and
using the distributed network model on the right
side of Rs. If it is necessary to use the distributed
network model for part of the network, then it is
absolutely necessary to be consistent for all of
the network.

When you switched to the lumped circuit model on
the right side of Rs, the energies balanced. When
you switch to the distributed network model on
the left of Rs, the energies will also balance.

The lumped circuit model is a subset of the distributed
network model. See: http://www.ttr.com/corum/ and
http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

Here's some quotes: "Lumped circuit theory fails because
it's a *theory* whose presuppositions are inadequate.
Every EE in the world was warned of this in their first
sophomore circuits course. ... Lumped circuit theory
isn't absolute truth, it's only an analytical *theory*.
... Distributed theory encompasses lumped circuits and
always applies."

> Where does the energy being absorbed by these ideal voltage
> sources go?

0+j0 ohms cannot absorb energy. As Eugene Hecht said:
"If the quantity to be measured is the net energy per unit
area received, it depends on 'T' and is therefore of limited
utility. If however, the 'T' is now divided out, a highly
practical quantity results, one that corresponds to the
average energy per unit area per unit time, namely 'I'."
'I' is the irradiance (*AVERAGE* power density).

You seem to have discovered that "limited utility".
You have an instantaneous power calculated over an
infinitesimally small amount of time being dissipated
or stored in an impedance of 0+j0. Compared to that
assertion, the Virgin Birth seems pretty tame. :-)

Are the beam and collinear isolated from the pole?
If so, there's probably no real problem.

If a mobile antenna is being used with the pole as
the counterpoise, then about half of the RF energy
flows in the pole. RF burns can be the result.

Roger Sparks wrote:
> This is much too arbitrary for me.

It's not arbitrary at all - it's the result of very
carefully chosen boundary conditions including specifying
a 100% 50 ohm system with ideal components. It agrees with
Roy's posting about ideal source impedances and short-circuits.

The bottom line is: If the distributed network model
is used to the right of Rs, it must also be used to
the left of Rs. Once the distributed network principles
are applied to the source, the results are the posted values.
Since no other values are possible, it is certainly not
arbitrary.

What *is* arbitrary is willy-nilly using the distributed
network model for part of the network and using the
lumped circuit model for the other part.

I have updated the diagram to the values that I calculated
for the shorted 45 degree line.

```
100v 50ohm 45deg
GND--------Vs----------Rs--------50ohm----------short
25w--> 125w--> 50w-->
<--25w <--25w <--50w
```

The net voltages and currents are the result of the
superposition of the component voltages and currents.
The forward and reflected power readings are what
an ideal directional wattmeter would indicate.

Try some of the farm supply places. We call them feed and seed stores around
here.

You can still get a lot of stuff made for electric fences in ceramic and
farmers often have to do their own power distibution so the y carry big
porcelan insulators with lag or SAE thread bolts. Getting to know someone
who works for the local PoCo helps.

Since a short causes a reflection, it seems that
(2) and (3) are essentially the same thing and
since 0+j0 cannot absorb energy and always
reflects energy, seems (1) can be discarded as
an over-simplification, something for which the
lumped circuit model is famous. For instance:

Given a loading coil installed in a traveling
wave antenna - reckon why EZNEC gives completely
different delays through the inductance when it
is modeled as a lumped inductance vs when it is
modeled using EZNEC's helix feature?

Very cool, Roy. Thank you for this, this is good information that makes sense to me. There is a lot in there to think about and apply to the application for which I'm analyzing this antenna.

When you talk about the current maximum and loss of a radial, you bring up another question. My 1/2 wave vertical is going to have a much higher feedpoint impedance than a standard 1/4 wave vertical. Let's say it's somewhere around 2000 ohms as compared to 40 or so ohms for a 1/4 wave. What effect does that higher feedpoint impedance have on the radial system? Does it relax the requirements for the number or radials or the length of them? Does it mask the loss that you'd have normally? Or do the "rules" of adding radials apply no matter what the vertical's input impedance?

Thanks very much.

Roy,

This is blowing my mind. What you said about ground loss peaking at some certain conductivity makes perfect sense but I never thought about it before as applied to a vertical antenna system like this.

Sure enough, I found a maximum. This is wild. We always think, "The better the ground, the better the antenna system," but it's not that simple. It's funny to think that really terrible ground can have an advantage over pretty good ground.

Next I'm going to play with the radial length so I can see the other effect you described for me.

Regards,

Al W6LX

Hi Al,

There are two sides to this coin and you are only looking at one.

Let's take for example the vaunted superlatives that are often tied to
swamp land, or even planting your antenna farm offshore (ah that
seawater!). There is more loss there than if you planted your antenna
farm on a 100 foot sand dune (think glass).

So, why do so many eyes mist up with the opportunity of being in a
swap or in the ocean? Launch angle.

That same high (lossy) conductivity is also responsible for what is
called the Brewster angle when it comes to vertical antennas. The
higher the conductivity, the lower the Brewster angle, the lower the
launch angle possibilities, the longer out to the first skip - DX!

Longer radials will not lower that Brewster angle unless you extend
them out very far with a lot of them (think of carpeting the soil out
with a copper mesh for several 10s of wavelengths).

So, returning to your comment:
>"The better
>the ground, the better the antenna system,"
Better ground may subtract power in the near proximity, but better
ground may also boost relative power at low angles. So, you need to
define what is meant by "better" because this is a choice of opposite
alternatives.

That's not correct. However, it is essential to align the segment junctions so they're directly across from each other when modeling closely spaced parallel wires.

We can calculate the voltage and current of an imaginary resistance, imaginary capacitance, imaginary inductance, imaginary current-controlled voltage source, imaginary ideal transformer, and ideal lossless transmission line. And we can calculate them for a perfect voltage source, too. From the voltage and current, we know the power, and from its sign the direction of energy flow. Certainly we can't know what happens to the energy which goes into the source. But why should we care? I can tell you, using the fact that an ideal voltage source reflects like a short circuit, the voltage and current in every forward and reflected voltage and current wave from turn-on to steady state of a transmission line/source/load system. At all times, the voltage across the ideal source will be invariant, as it must be, regardless of the current into and out of it. And I can show exactly where every erg of energy is at every instant in any component and at every point along the transmission line. I submit that any analysis technique which can't do this without knowing what happens to energy entering the source is inferior.

Roy,

One question:
Down the list is my posting FINAL PLAN.
Is it possible with EZNEC to simulate it?
It is made of transmission line (partly)

Yes or No is enough.
I have the DEMO version.

Hi Al,

From my experience, and simulation, a halve wave vertical has less stringent radial requirements. The current reduces with a factor of about sqrt(2000/50)= 6 (16 dB).

The result is less loss in the vicinity (near field) zone of the antenna. Far field maximum of radiation (elevation) will virtually not change because of canceling effect of reradiated field from ground below the (pseudo) Brewster angle. Because of the somewhat higher radiation center with respect to a 1/4 wave, the elevation of maximum radiation will be somewhat less. Off course when you have high ground conductivity (for example fertilized wet soil), you will have maximum radiation under lower elevation.

It is likely that in the end the produced field under relative low elevation will be higher than that from a horizontal dipole.

Elevated radials give less ground loss. At high frequency, the relative epsilon becomes important. A High dielectric constant and low conductivity may result in less loss. At high frequency a larger part of the current goes to the capacitance of the ground instead of the loss resistance (in a parallel equivalent circuit). See it as having a low loss dielectric under your antenna.

Hope this help you a bit.

Sorry, a plumber's delight design is where the support
pole is attached to a voltage node on the antenna so no
RF current flows in the pole. The alternative is to
insulate the balanced Yagi from the pole.

Thanks for the explanation.
For the best performance from the Yagi would you recommend to insulate it
from the pole as a standard practice for safety and performance?

Thanks

Yes, a simulation should be reasonably accurate. The segmentation limitation of the demo version will probably reduce the accuracy some, but you'll be able to get a very good idea of how it will work.

>

It is arbitrary because when using the short circuit model, you limit the discussion to only one example of transmission line termination--the example of a low impedance on one end of the line and a higher impedance on the other. As you well know, two additional examples of transmission line termination are possible--the transmission line impedance is higher (or lower) than the termination at either end.

It is also arbitrary because the reflected wave information is useless. Any reflection from the source is folded into the sine wave to form one wave, which becomes the forward wave. The only real accomplishment from the exercise to to shift the frequency for a one cycle "bump", and that accomplishment does more to introduce confusion than contribute to better understanding.

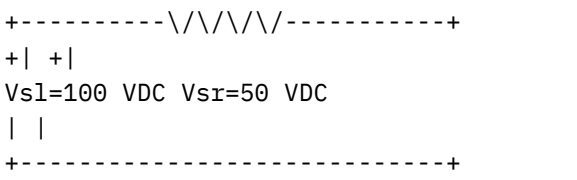
It is a good thing I checked the original references, otherwise
I would have had to assign Corum and Corum immediately to the
flake bucket where they could join some of the other contendors
on this group. But no, it turns out they have the appropriate
qualifications on all their statements about when it is
appropriate to use a lumped analysis and when it is not. And
when is lumped okay, when the physical dimensions of the

elements can be measured in small fractions of a wavelength.
Nothing new there, most of us know that.

Let me remind you of the circuit at hand:



Firstly, there are no inductors to cause any sort of difficulty.
Secondly, it is constructed of ideal components, which have the
luxury of being infinitely small.
And thirdly, it is a DC circuit so the two points above do not
matter any way.

So we are back to the question you keep dodging...

> > Where does the energy being absorbed by these ideal voltage
> > sources go?
>
> 0+j0 ohms cannot absorb energy.

Now that is a non-sequitor. The element absorbing energy is an
ideal voltage source, not a resistor.

> As Eugene Hecht said:
> "If the quantity to be measured is the net energy per unit
> area received, it depends on 'T' and is therefore of limited
> utility. If however, the 'T' is now divided out, a highly
> practical quantity results, one that corresponds to the
> average energy per unit area per unit time, namely 'I'."
> 'I' is the irradiance (*AVERAGE* power density).

It is a DC circuit. This means the instantaneous value is
the average value.

(But poor Hecht, here he is saying power is more useful than
cumulative energy, and you misinterpret him to be comparing
instantaneous to average. And is it the distribution over
the area that is being averaged, or the distribution over
time?)

> You seem to have discovered that "limited utility".
> You have an instantaneous power calculated over an
> infinitesimally small amount of time being dissipated
> or stored in an impedance of 0+j0. Compared to that
> assertion, the Virgin Birth seems pretty tame. :-)

Again, it is a DC circuit since we have had to go back
to learning the fundamentals of ideal voltage sources.

But back to the simple question...

Where does the energy that is flowing into the ideal DC voltage source on the right go?

If no energy is flowing into the ideal voltage source on the right, where is the energy that is being continuously provided by the ideal voltage source on left going? Of the 100 W being provided by the ideal source on the left, only 50 W is being dissipated in the resistor. Where goes the remaining 50 W, if not into the ideal voltage source on the right?

Dunno 'bout standoff insulators but Davis RF carries porcelain compression insulators: http://www.davisrf.com/. I use their #10-72 (Daburn's PN) for dipoles, supported by ¼" diameter rope. They don't have what I would call good descriptions or even photos but you can search for a part number on Daburn's website: http://www.daburn.com/

I have a 60ft garden and my maximum height I can go is only 20ft. I would like to TX on 80-40 and on 160 if possible but I might be asking the impossible with the 160m..
I do not have a ground system in place. I can put some earth rods in and some surface wire but I have no way of putting any wire into the soil itself. So I am a bit limited.

I have a 150ft of flexweave wire that is uv plastic coated to play with.
I think I have three choices to chose from at the moment.
I can use the SGC-230 with an inverted L.
I can use the SGC-230 with an inverted L with homebrew traps built in.
I can use an inverted L with homebrew traps built in but without the SGC-230.

What would be the best choice and why?

Many thanks

You wrote the program, so I am not arguing with you, I will check it
out again. I sure feel I remember that being a restriction. Funny
thing is, that I haven't set learning the program to a higher priority
since I didn't think it would model what I want to experiment with,
which is parallel wires/poles.

I'll have to look into that more.

Thanks for the heads up.

BTW what is the upgrade cost for 4.0 and 5.0 from 3.0?

Thanks

I am going to give it a WAG and suggest you would be better off
without the traps. Can the tuner be mounted in the weather? If so,
put it as close to the wire as you can and as high as possible.
If not, does if feed twin-lead? If so, could you make a 150 foot
dipole and feed it with twin-lead to the tuner? I would like that
idea best. Even 300 ohm twin lead from Radio shack would be good.

The inverted L seems to prefer ground radials, but a dipole or random
wire may be better. If you can go up and only in one direction, could
you run 300 ohm up and tap one end? this would be an end-fed Zep, i
believe, and the tuner should tune it.

My thoughts are that you will be better off with as much of your 150
feet of wire horizontal in the air rather than in the inverted L
configuration, given your stated restrictions.

BTW, my tuner is manual, but I operated from a 130 foot dipole about
100 feet high fed with RS tv twin-lead for about a year with 100 watts
and did very well.

Barrett,
End fed wires and/or inverted 'L's tend to work much better with an adequate ground system. That 'adequate' is very variable, more is better than less in general. Something like 150 feet is not exactly 'adequate' enough for a 'good' 160 meter 'wire'. Not exactly 'bad' for the higher bands though. A surface ground system will probably do as well as a buried one. Just watch it when mowing the grass!
Either of your options are going to be marginal for 160m. Which would be best? Good question! Hope you let us know the answer when you find it. While putting that tuner at the feed point is almost always the 'best' way of doing it, it's also the hardest. I'm afaid 'practical' wins out over 'best' in most cases.
Not much help, huh? You're right, it isn't. 'Best' is always dependent on the particular circumstances present. Good luck.
- 'Doc

It is not arbitrary - it is what it is. All of the
source impedance, Rs, is separated from Vs. That
leaves only a 0+j0 dead short impedance possible
for the series source. If it was some other value,
the distributed network model would still work.

> Any reflection from the source is folded into the sine
> wave to form one wave, which becomes the forward wave.

Yes, in exact accordance with the distributed network
model. What it means is that the source is not delivering
the folded-in reflected energy at the time the reflected
energy joins the source signal. Since I don't see that
energy in Keith's equations, chances are that is why
they didn't balance.

You are missing an important observation here. When the energy from the reflected wave folds into the forward wave, any further analysis is a replication of the first analysis. Nothing new is learned.

I think what you want to see is a source matched to the load, so that all the energy flows one way, to the resistor Rs. Your proposal is to allow/force reflectons from the source Vs so that effectively, the resistor Rs becomes the only load. This is then a demonstration/proof for what?

4397. Re: Efficiency of 200-ohm hairpin matching

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-19 17:02:43 UTC
From: Antonio Vernucci <vernucci@tin.it>
Message-ID: <480a25a6$0$40214$4fafbaef@reader5.news.tin.it>
Source record: 25919

After running the required simulations it was possible to conclude the following:

- the antenna impedance can clearly be transformed into 50 ohm or into 200 ohm by just changing the driven element length and the hairpin length. By selecting the proper lengths, an identical SWR curve can be obtained for the two cases, this meaning that the matching system impedance has virtually no influence on the SWR bandwidth of the antenna under simulation

- however, for a given RF power, in the 200-ohm case the RF current in the hairpin is about 1.8 times higher than in the 50-ohm case. This means that in the former case the power lost in the hairpin ohmic resistance would be about 3.2 times that of the latter case.

Perhaps you're remembering a restriction with MININEC-based programs, which had problems with close spaced parallel wires.

Hello Tony,

Probably you convinced yourself for 100% that the antenna limits the
bandwidth.

One can generally say when the bandwidth of the L network is far
greater then the antenna bandwidth (without matching, with respect to
a reference impedance equal to the resonance [real] impedance), the
overall BW is just a little less then the antenna bandwidth.

Or you can say when the antenna Q is far higher then the Q of the
matching network, overall Q factor is determined by the antenna. The Q
of an L network is about sqrt(Zin/Zout −1), when Zin<Zout, uses
sqrt(Zout/Zin-1). For a step from 20 to 200 Ohms, the VSWR=1.5
Bandwidth is about 11% (5.72 MHz in your case)

A nice exercise can be modeling your antenna's impedance (without
matching) as a LCR series circuit and put this into a lumped circuit
simulator (for example a PSPICE simulator). Some simulators allow
direct entry of S-parameters.

Now you can add every other component (also lossy and lossless
transmission lines) and see the effect on the overall BW.

As other people said, the Q of a hairpin made of 5…10mm tubing is over
100. As the BW of your L match is far below that (also for the 200 Ohm
case), losses in the hairpin are that low, that they can practically

not be measured via field strength measurement. So 3.2 times higher then in the 50 Ohms case is still negligible.

After all the calculations and simulations, I hope your 6m Yagi is still useful for you.

Best regards,

Wim

Could one use a length of iron or copper pipe as an RF choke on coax or speaker leads? I've seen lengths (1m) of ungrounded copper pipe on coax used as lightning chokes.

So much disinformation by W8JI School of DC circuitry :-)

Modeling various configurations shows benefits of good ground, especially for taller than 1/4 wave radiators.
Myth that half wave radiators do not need ground is spreading like snake oil wild fire. They need it but "looking" for it further out, not just at the base.
I will anytime trade good ground (mirror) for lossy (RF sponge) ground. Its just where the radiator is "looking" for the mirror, taller one - further out, enhancing signals at lower angles.
3/8 vertical with some 3/8 physical length radials start morphing into far field.

I don't know about iron or copper, but in the early 90's someone suggested that a tube of steel wool could effectively replace the ferrite beads normally used in choke baluns. That was proven to be a bad idea. I would suspect that iron or copper pipe would be far less effective than ferrite beads. If you check the choking impedance of say 50 beads vs. an equal length of pipe, you will find the beads vastly superior.

There are two quite separate ways which ground affects a vertical
antenna's performance.

The first is loss due to current returning to the antenna base when the
antenna is grounded, or induced in the ground under an elevated radial
system. To minimize loss, you want as much of the current to flow
through radial wires as you can. The power loss is I^2 * R. For a given
power input, I is much lower for a half wave bottom fed vertical than a
quarter wave bottom fed vertical. So the loss due to the conducted or
induced current is much less, and you can get by with a much simpler
ground system with the half wave vertical and still have low loss.

This ground loss is usually the chief determining factor of a vertical's
efficiency.

The other effect of ground is that the field from the antenna reflects
from it some distance from the antenna. The reflected field adds to the
directly radiated field to form a net field which is different at each
elevation angle. This is a major factor in determining the antenna's
elevation pattern. The conductivity and permittivity (dielectric
constant) of the ground affect the magnitude and phase of the the
reflected field, so the pattern changes with ground quality. In general,
the more conductive the ground the better the low angle radiation.
However, you can't compensate for this factor when the ground is poor by
improving the ground system. The reason is that the reflection takes
place much farther from the antenna than nearly any ground system
extends. And low angle radiation, where the improvement is most needed,
reflects the greatest distance away. The only way to improve the
situation is to move the antenna to a location where the ground is
better, which usually isn't possible or practical.

Because of the two separate effects, the overall field strength might be
better or worse as the ground conductivity improves, and it might even
be better at some elevation angles and worse at others.

Very nicely put, Roy. Although I "knew" this in the recesses of
memory, the refresher will stick with my memory more, now. Thanks.

In my case, I am considering the use of a vertical at a new residence
built on sand. Since I am not concerned about low angle radiation
characteristics, the Half Wave may be something to consider..... giving me
a fairly efficient vertical operation with some NVIS characteristics.

Hi Ed,

Efficient? A vertical has almost no Near Vertical radiation for Near
Vertical Incidence Skywave. You can get along with "almost no," or
you can simply use a low horizontal which would exhibit "a lot of"
Near Vertical Incidence Skywave.

Good ground, bad ground, radials, no radials won't change efficiency
much for the vertical's incidence overhead (there's a hole in that
pattern).

Richard,

By "efficient" I was referring to the transfer of power.... to a
presumed 50 ohm antenna input, not to any radiation characteristics !
As I understood it, a half wave vertical can give me this, with a
little effort. I also understood it to have a fairly high take off
angle.... which will certainly give me better in-state coverage than a
good low angle takeoff would..... wouldn't it?

Yes, I know a proper NVIS antenna would be far better than this....
that is why I used the term "some NVIS" characteristics.

Ed,

It won't be suitable for NVIS, as you can see from a model.

All the radiation from an antenna isn't concentrated at some "takeoff angle", but radiates at all angles at various amounts. That distribution is known as the "elevation pattern" and trying to replace it with a single "takeoff angle" value loses nearly all the information about how and where the antenna radiates. The half wavelength vertical radiates very little above about 60 degrees elevation angle regardless of the ground characteristics.

news:al5Oj.17661$_h7.16042@newsfe05.ams2:

> I've just downloaded EZNEC v. 5.0 demo.
> I'm only just starting to learn the basic concepts from the beginning.

Okay Barrett,

One of the basic concepts that is helpful is the "wavelength".

The speed of an RF signal in free space is the speed of light.

Imagine a pure RF sine wave. Starting at zero, the sine will increase to maximum, then turn around, cross zero again, then go to the other maximum, and then return to zero. The distance traveled while that happens is the wavelength. Pretty simple, that, but all the other parts are related to it. A lower frequency travels further before returning than a higher one does.

Now in order to have an antenna that will cooperate with our transceivers, it needs a particular impedence, or near to it. What most equipment uses is 50 ohms impedence. Some equipment use 75 ohms, but nothing we're interested in Amateur radio.

So if you are designing a single band antenna that uses coax, you'll want to hit around that value of impedence.

There is a relationship between the length of the antenna and the wavelength. In the case of a typical antenna for amateur radio use, the dipole, you'll end up with around a half wavelength antenna, 1/4 wavelength on each side to get near that impedence. Other antennas may use more complicated ways of coming up with the proper impedence.

These are generalizations. There are some other aspects, such as changes in the speed of the RF through cables and insulated wires being different than in free space, but what I gave you so far is pretty much the basic basics.

I'm posting steady-state values. If it is already
steady-state, nothing new is needed. The point is
that some of the steady-state forward energy is
not being delivered by the source.

> Your proposal is to allow/force reflectons from the source
> Vs so that effectively, the resistor Rs becomes the only load.

No, the resistor Rs is not the only load. The resistor
plus the rest of the network is the load. With a 45 deg
shorted stub the load is 50+j50 as you previously
reported.

The garden is only 60ft long, so fitting in 150ft won't work here. I could
make a Z up but the end of one end would have to drop to garage roof height
(9ft) and it would put the other end of the Z running (clipped onto the
plastic gutter). This would put the Aerial very close to the house and very
close to the neighbours TV and radio aerial.

I could do but my nax height would be 20ft would this work? Also I have a 20ft scaffold pole note grounded that the G5RV is supported by won't this interfere with it?

Yes indeed, the simulation verified that my FINAL PLAN is working OK
Two very clean resonances at 3.6MHz and 10.1MHz SWR abt 1.3 on both bands
Antenna length only 26m instead of normal 41m for 80m dipole.
For the stub section I used 0.003m=3mm spacing and 1.5mm insulation on 1mm
wire DielC 2.6.

Is there any possibility in EZNEC to calculate how long is quarter WL on
10.1MHz
with these stub variables?

By using transmmission line objects it could have been possible to use the
VF of line 0.73.

I did run out of segments to simulate tri-band version with additional
parallel dipole.

All simulation was made in free space and probably needs some minor tuning
in real life.

Roy, didn't the experiments of Brown, Lewis & Epstein of RCA in ~1937 show that the h-plane field measured 3/10 mile from a vertical monopole of about 60 to 88 degrees in height, over a set of 113 buried radials each 0.41 WL, was within several percent of the theoretical maximum for the applied power as radiated by a perfect monopole over a perfect ground plane? And conductivity at the NJ test site was poor -- 4 mS/m or less.

That tends to show that the fields radiated at very low elevation angles also will be close to their theoretical values when measured at this radial distance, even though ground conductivity at the antenna site is poor. The relative field (E/Emax) for radiators of these heights and propagation paths approximately equals the cosine of the elevation angle.

The greatest radiated fields always will be directed in or near the horizontal plane when measured/calculated for such conditions. This also will be true for any monopole from infinitesimal to 5/8 wavelength in height, although the elevation pattern of monopoles from /4- to 5/8-WL no longer are described by the cosine function (see http://i62.photobucket.com/albums/h85/rfry-100/MWElPatComparison.jpg).

Elevation patterns show maximum relative field centered at various elevation angles above the horizon, when those fields are measured at progressively longer radial distances from the monopole, due to the propagation loss for the surface wave over other than a perfect, flat, infinite ground for those ranges. Earth curvature and terrain diffraction add to those losses for longer surface wave paths over real earth, and for very great distances the h-plane relative fields falls to ~zero.

But that pattern shape is not the pattern shape originally radiated by the monopole, it also includes the effects of the propagation environment at the range where it was measured (or calculated).

If this were not true then MW broadcast stations would have essentially zero coverage area for their groundwave signals.

Maybe I should change the subject line, but here goes.
First of all, i am fishing for information, not challenging anyone's
intelligence.

I understand from books I have read, that a ground mounted vertical antenna needs many radials. IIRC, the point of diminishing returns on adding radials falls somewhere between 64-128 radials. I imagine the best radial-based ground I could have for 20 meters would be a solid copper disk with about 16 feet radius, give or take. However, I recall in the ARRL Antenna handbook, not the latest version, but one prior to this one, there is no noticeable difference between a raised ground plane antenna with 4 elements as opposed to 128. (From here, or another antenna forum, I heard for the first time that it holds true for two radials.)

I am still trying to figure out why so many radials are needed on the ground and a few feet higher so few are needed.

Actually, more important than the why, is how high is high enough to reduce the optimum number of radials? For example, i want to build a 20 meter vertical. I understand the best place for it is on top of a 100 foot+ tower, but somewhere in between, there has to be a place where 4 radials above ground is noticeably better than the same 4 radials on the ground.

Another point I have heard in the forums, but not confirmed, is that a reduced size vertical element doesn't gain much by adding radials longer than the antenna is high.

I believe that in order for a pipe to be effective, it would have to
be some distinct fraction of a wavelength of the signal you want to
block. If you have problems with 80 meters, it could be a very long
pipe.

On the other hand, the ferrite beads can cover many more frequencies
in much less space.

> are the reflections? Where is the average interference
> equal to zero?

Your explanations are predicated on a misunderstanding of
the behaviour of ideal voltage sources. Despite your
protests to the contrary, ideal voltage sources can, and
do, absorb energy.

The discussion needs to digress to address this fundamental
misunderstanding since this misunderstanding renders all
else moot. And so...

Let me remind you of the circuit at hand:

```
50 ohms
+----------\/\/\/\/-----------+
+| +|
Vsl=100 VDC Vsr=50 VDC
| |
+-----------------------------+
```

And we are back to the question you keep dodging...

Where does the energy that is flowing into the ideal
DC voltage source on the right go?

If no energy is flowing into the ideal voltage source
on the right, where is the energy that is being
continuously provided by the ideal voltage source on
left going? Of the 100 W being provided by the ideal
source on the left, only 50 W is being dissipated in
the resistor. Where goes the remaining 50 W, if not
into the ideal voltage source on the right?

Once it is agreed that ideal DC voltage sources can indeed
absorb energy, we can discuss the same for ideal AC voltage
sources. Once that is agreed, we can return to the
discussion of your 'interference free' circuit.

I came across this web site http://www.paulnic.com/ekrs/aom_sep04.htm after searching for weeks on how to construct a pair of 80m conductor add-ons. I might go down this root short term, just to get on the air.

I wonder if I could use some 42 strand speaker wire to make the conductor or will I have to order some enamelled SWG20 copper wire as stated?

Thanks

==========
Instead of an approx 16 ft radius disc ,you might consider an area
covered with chicken wire mesh with the antenna in its centre.If that's
laid on a lawn the grass will quickly grow over it . In a few weeks time
the wire mesh will no longer be visible and the lawnmower can just run
over .
A Butternut (vertical)antenna with a mesh ground plane compared with
none gave an improvement of 1 to 2 S points on 20 ,15 and 10 m.

Do you have the ARRL version of the demo, or just the one downloaded
from EZNEC?

If you have the ARRL version, you can modify a sample design and get
all the segments you need; you just can't save the antenna.

Hi Buck,

I downlowded the Demo and it is limited to 20 segments.
My ARRL antenna book is so old that it had no EZNEC.

>>
>>Perhaps you're remembering a restriction with MININEC-based programs,
>>which had problems with close spaced parallel wires.

I apologize. I think I mentioned that your program had limitations
that would not allow me to model what I wanted, which in my case is
close parallel elements. I was pretty sure that was why I quit using
it. Maybe there was another reason.

Whatever the case, I have, and still do, appreciate hearing your
knowledge and information.

It isn't my desire to design a new earth-shattering antenna or to
super-fine tune a yagi, but to use the rules of thumb in antennas to
build antennas with specific purposes in mind such as for portability,
maximum number of HF bands with minimal losses, and maximum gain with
minimum cost.

I gave up on an all-band HF antenna. there are just too many bands
these days. I built one from 80 - 6 meters in parallel dipole format.
It became such a bear to handle that it wasn't worth the effort trying
to keep it untangled, not to mention the weight of it.

I guess I digress.

Ok, Barrett,

First of all, I missed your british accent the first time around, and
I have also read the instruction manual that came with the tuner.

Now that I understand you and the tuner (coupler) better, I can make
better informed recommendations.

>>>I have a 60ft garden and my maximum height I can go is only 20ft. I would
>>>like to TX on 80-40 and on 160 if possible but I might be asking the
>>>impossible with the 160m..

Your coupler says it only needs 23 feet to tune 160m. At that rate,
you would not be one of the big fishes in the pond, but you would be
there.

>>>I do not have a ground system in place. I can put some earth rods in and
>>>some surface wire but I have no way of putting any wire into the soil
>>>itself. So I am a bit limited.
>>>

You might have more of a ground than you think. hang in there...

>>>I have a 150ft of flexweave wire that is uv plastic coated to play with.
>>>I think I have three choices to chose from at the moment.
>>>I can use the SGC-230 with an inverted L.
>>>I can use the SGC-230 with an inverted L with homebrew traps built in.
>>>I can use an inverted L with homebrew traps built in but without the
>>>SGC-230.
>>>
>>>What would be the best choice and why?

The best choice is the one that will give you effective communications
given your resources and abilities. I think you will do well.

>> I am going to give it a WAG and suggest you would be better off
>> without the traps.

your coupler supersedes your need for traps.

>> Can the tuner be mounted in the weather? Yes
See Page 7 in the users manual. Can you acquire or spare a plastic
garbage can?

SNIP

>If so, could you make a 150 foot
>> dipole and feed it with twin-lead to the tuner? I would like that

>> idea best. Even 300 ohm twin lead from Radio shack would be good. This is
>> out due to getting it through the house wall.

I assume you can get a piece of coax out from the radio to the
coupler?

>
>

>
>
> I could do but my nax height would be 20ft would this work? Also I have a
>20ft scaffold pole note grounded that the G5RV is supported by won't this
>interfere with it?

:) :) :)

To me, this is your ace in the hole :)

See the diagram at the top of page 7?

Here is what I would do assuming the trees or other supports
cooperate.

Get a protective cover for the coupler as shown. Mount the coupler as
high up the pole as you can. Ground the coupler to the pole well
where you mount it, and cover the coupler as in the diagram.

at the base of the pole, set one of the ground rods and ground the
pole to the rod. You don't need any wire going from the tuner to the
ground rod as the scaffold pole will be the conductor.

From the tuner, stretch your wire out as far as you can to the other
supports. Weave it around, if you must, but try to get as close to 80
feet of wire strung out as possible. Make a "T" in the wire if
necessary giving the wire three points, one at the tuner and two going
different directions. For me, the more wire, the better. The more
spread out, the better.

Now, when you reach your limit, take the rest of the wire and make as
much of ground radials as you can as you see in the diagram on pages 7
& 16.

If you can't run them far, go as far as you can.

The second alternative? Replace your G5RV with the installation shown in the diagram on page 17.

If you can't raise the coupler up the pole very high, you could mount it as high as possible on the pole, and run the hot lead up beside the pole (separated as far as possible) loop it thru an insulator near the top of the pole and continue trying to get as much wire out as possible.

I imagine that if I walked thru your garden and saw it in person, I would make different suggestions, but based on my perception of what I have never seen, I can only take a bit of a guess.

Let me know how it goes.

Thanks

Probably you convinced yourself for 100% that the antenna limits the bandwidth.

Yes, I had overestimated the effect of the matching system, and, as you say, the antenna Q is far higher then the Q of the matching network. The fact that the capacitance (corresponding to the capacitive reactance of the shortened D.E) varies with frequency does not change things.

As other people said, the Q of a hairpin made of 5ï¿½10mm tubing is over 100. As the BW of your L match is far below that (also for the 200 Ohm case), losses in the hairpin are that low, that they can practically not be measured via field strength measurement. So 3.2 times higher then in the 50 Ohms case is still negligible.

I agree with the conclusion

After all the calculations and simulations, I hope your 6m Yagi is still useful for you.

Yes, after precisely tuning the D.E., it shows a good SWR all over the band of my interest. Nevertheless, before mounting the antenna, I would not have suspected such a narrow SWR response.

Buck, here are some photo's of the antenna at the moment. The new one will have to be in a similar position.
http://www.hobby.pwp.blueyonder.co.uk/antenna/3.jpg
http://www.hobby.pwp.blueyonder.co.uk/antenna/4.jpg

Not sure what to cover the SGC with to keep the rain out. Plus it will be in direct sun all day on top of the pole. Garden is Roughly North to south.. South being at the pole end of the garden.
I can disconnect the homebrew G5RV and move the ugly coax balun I made up to the pole and add some new coax in-between. I know its a lot of connections but it will have to do for the time being.

Hope this helps.

Thanks

I believe we've discussed this before, so I'll be brief.

Their calculation of the field at the receiving site when the radial system is perfect was adjusted for the effect of ground wave attenuation caused by the imperfect ground conductivity. If the ground between the antenna and receiving site were perfect, the field strength would have been greater.

Also, I'm speaking of sky wave. Ground reflection isn't a factor in determining surface wave, which is what they measured and which isn't of interest to most amateurs.

As I thought you were aware, the surface wave propagates considerably
differently than the sky wave.

It would be a mistake to design HF antenna systems based on optimizing
surface wave propagation as AM broadcasters do, unless you desire
communication for distances not exceeding a few miles.

> true for two radials.)

When a ground system is a long distance above ground, only two radials are needed for high efficiency and a circular pattern at zero elevation angle. The pattern does become non-circular at higher angles, which can be prevented by adding two more radials. A ground system which is above but close to the ground requires fewer radials for good efficiency than one with radials which are buried or much closer to the ground.

> I am still trying to figure out why so many radials are needed on the
> ground and a few feet higher so few are needed.

The ground is very lossy. When the radial system is on or in the ground, current flowing to the radials is forced to flow through the lossy ground.

That's a good question without a single good answer. It depends at least on the ground conductivity and permittivity (down to a considerable depth), frequency, and radial length. Modeling can give you a good idea of the tradeoffs, although the very simple minded ground model might not be adequate to make a very accurate comparison.

> Another point I have heard in the forums, but not confirmed, is that a

I don't believe that's true. I'll gladly consider any supporting evidence. Hearing something on forums is among the worst justification for believing it, in my opinion.

Here we are again forgetting that we are dealing with standing wave circuit
and cos/sin current distribution along the elements. Half wave vertical
might have low current at the base but quarter wave away it will be max
(assuming half wave elevated electrical radial). The radiation pattern is
formed between the radiator and radials (and how they are affected by ground
under).
Radials close to ground couple to it and depending on ground RF quality we
are dealing with decent reflecting mirror or "RF eating sponge".

Previously, about BL&E's 1937 measurements:

> Their calculation of the field at the receiving site when the radial
> system is perfect was adjusted for the effect of ground wave attenuation
> caused by the imperfect ground conductivity.

Anybody: Just wondering -- how does this conclusion flow from the findings published in the 1937 I.R.E.paper of BL&E?

The theoretical (not measured) BL&E groundwave field at 1 mile for 1 kW radiated from a perfect monopole over a perfect ground plane as shown in the BL&E I.R.E. paper is not the equivalent/adjusted field they measured from the monopole heights they tested. But, as BL&E published, the groundwave fields they measured from these real monopoles over real earth was within several percent of that theoretical maximum, when working against 113 buried radials each of 0.41WL -- even for the poor conductivity at/near their antenna site.

> Also, I'm speaking of sky wave. Ground reflection isn't a factor in
> determining surface wave, ...

But neither theory nor practice supports this, does it? If so, then the groundwave fields that BL&E measured at 3/10 of a mile would have been at least 29.3% less than that theoretical maximum field, which included a perfect (3 dB) ground reflection -- not just the several percent they measured. And this measured performance just beyond the near field radius has been re-proven in thousands of groundwave r.m.s. field strength measurements of AM broadcast stations over many decades since the BL&E work.

> It would be a mistake to design HF antenna systems based on optimizing
> surface wave propagation as AM broadcasters do, unless you desire
> communication for distances not exceeding a few miles.

Just to note that since the 1930s (at least), AM broadcasters have been aware of the effects of the differing propagation characteristics of groundwaves and skywaves. This is evident in the fact that most 50 kW, fulltime, AM broadcast stations in the US use a radiator height that minimizes the self-interference of their skywave with their groundwave, so as to ~maximize their interference-free coverage areas when skywave propagation occurs. The great majority of these stations use a monopole radiator height of about 195 degrees.

>
If you used 120 radials on the ground as optimum, even raising only
1/8 wave off the ground will enable one to reduce the number of
radials
to equal the same performance.
But... You will still probably need at least 60 radials at 1/8 wave up
to equal the 120 on the ground. So even at that low elevated height,
4 radials is better than 4 on the ground. But... Still not very
good.. :/
At 1/4 wave in height, you will need about 8-10 radials to equal the
120 on the ground. Only when you approach 1/2 wave in height can
you use 2-4 radials and have the same appx ground losses as the
120 on the ground.
You *must* think in terms of wavelength off the ground, not just feet
in general. A 160m vertical will need to be about 250 ft off the
ground
to be able to use 2-4 radials with optimum results.

A 10m vertical can be 16 ft off the ground with 2-4 radials and have
the same performance.
If you had the 20m vertical at 16 ft, "1/4 wave", and used 4 radials,
it would be equal to a ground mount using about 60 radials.
Pretty decent antenna.

In the case of your 20m vertical, it will need to be 32 ft high to
be able to use 2-4 radials and appx equal 120 on the ground.
But a 20m vertical at 8 ft off the ground with 4 radials will
be better than the same vertical on the ground with 4 radials.
But if you want that 8 ft high vertical to equal 120 on the ground,
you will need about 60 or so, being it is only 1/8 wave up at that
frequency. This would give pretty decent performance.
Much better than the 4 radials at 1/8 wave up where 4 radials
is equal to about 8-10 on the ground. Neither one of those
is going to set the woods on fire..

Obviously, an elevated multi band vertical with radials for
each band will have varying degrees of ground loss depending
on the band in use at the time.
If you had a multi band 1/4 wave vertical "GP" at 32 ft, and had 4
radials for each band, you would have much less ground loss on
10m, than on 80m.
On 10m, it's 1 wavelength, and just 1 radial will be enough to
make an efficient antenna, except you have a dipole.
If you use two radials 180 degrees apart, that should actually
be a tad lower ground loss than 120 radials on the ground
being it's at 2 wavelengths up.
On 20m, it's at 1/2 wave up, and still very low loss.
At this point the 4 radials should be very close to
the 120 on the ground mount.
On 40m, it's at 1/4 wave up, and the 4 radials will
be equal to about 50-60 on the ground.
The antenna will still work quite well.
On 80m, it's at 1/8 wave up, and the 4 radials
would be about equal to about 8-10 on the ground.
A good bit of loss on that band. You will be able to
operate, but not with the gusto of the higher bands. :(

Maybe this will give you an idea of the appx level of loss
for a given number of radials at certain heights, vs the 120
on the ground. The most important thing to remember is
to think in terms of wavelength off the ground for the band
to be used.

>
> Another point I have heard in the forums, but not confirmed, is that a
> reduced size vertical element doesn't gain much by adding radials
> longer than the antenna is high.

Nope, I don't really agree. In fact, I think using the shorter
radiator makes the use of the lower ground loss radial set

even more important and worthwhile if you are trying to
approach full size performance.
You would see a difference I'm fairly sure.
BTW, a lot of the info I just wrote a novel about came
from the Bill Orr handbooks. He has sections on the subject,
and also graphs that match the levels of loss I mentioned
at the various heights.
In testing various verticals, including a full size 40m ground
plane which I could vary the height, I've never seen anything
to show his data is incorrect. It's from one of those blasted
books Art has problems with, but I happen to trust it as fairly
accurate.
All this pertains to the usual 1/4 wave elevated ground planes
vs a ground mount.

BTW, using a larger number of radials will not
improve the ground conditions of the far field,
but being that improving the efficiency of a given
height vertical improves the gain equally in all directions,
you should see an improvement for all types of propagation.
The ground wave, space wave, and sky wave will all
improve by increasing antenna efficiency.

Make that one wave up for 10m.. :/ But the rest should still apply.
Two should be slightly lower loss than the 120 on the ground,
being 20m is the frequency where they should be about equal.
I was rereading all that to see if I molested any numbers..
I knew I'd find one.. :(

Does it have to be a T shape and why?
How important is it to make all angles at least 90 degrees?

I have neighbours both sides of my house. My neighbours to my right looking down to the pole is ok with the wire antenna but the neighbours to my left, I'm having problems with.I have a feeling that they do not want anything near there side and truth be know they would rather not see any of it. I'm sure they had some thing to do with the planning officer paying a visit to my house about 12 months ago, when I had a I-max 2000 antenna for 10-18Mhz up on a 10ft pole on near there side So I have to try and keep the wire to the one side of my garden if possible.

Thanks

From the "IEEE Dictionary":

"Absorption: (2) A general term for the process by which
incident flux is converted to another form of energy,
usually and ultimately to heat. (4) The irreversible
conversion of the energy of an EM wave into another form
of energy as a result of wave interaction with matter."

By what mechanism does an ideal source with an impedance
of 0+j0 manage to dissipate heat? Since the energy absorption
by the ideal source is *irreversible*, where is the heat
(or other form of energy) stored and for how long?

Long ago, I discovered that anyone can become an "expert" on the
internet by making a statement and having someone else agree with them
or back them up. This is, of course, why I included the statement
"but not confirmed."

Very recently I heard a conversation on the air between a ham who was
"elmering" a new ham and another ham. The "elmer" was trying to help
the new ham convert a "vertical dipole" so it would operate on HF. It
was rather confusing for a bit until he better described it. It
turned out to be some kind of VHF ground plane antenna.

I understand ignorance.... but this worries me.

Finally, you have got the correct answer.

Having accepted that ideal voltage sources can remove energy
from a circuit, you can now re-evaluate your explanations.

With an ideal voltage source being capable of removing
energy, it should no longer be necessary for you to
propose strange notions of energy flowing through an
ideal voltage source and bouncing off the ground.

Just as ideal voltage sources can provide energy to a circuit,
they can also remove energy from a circuit.

Feel free to substitute the word of your choice for 'remove'.

Dissipate is not a good choice since it usually implies
conversion to heat.

Absorb is not a good word for you, since you can find absorption
in the IEEE dictionary and it also suggests conversion to heat.

The thesaurus (http://thesaurus.reference.com/ suggests 'consume',
'assimilate', 'digest', 'imbibe',
'take up', 'sop up', and 'devour'.

Pick the word that you find least confusing.

Recalling that an ideal voltage source can provide (deliver,
furnish, supply, transfer) energy to a circuit, we need a
non confusing word to describe the concept that an ideal
voltage source can also remove energy from a circuit.

A word that gives no hint about where this energy goes would
be best, since, just as we do not know where the energy
that an ideal voltage source delivers to a circuit comes
from, we do not know where the energy that an ideal voltage
source removes from a circuit goes.

Barrett,
A little speculating.
Is there any chance of finding an 'anchor' point on your home's roof? Nothing very spectacular or noticeable from the 'street' side, but one that would add a few feet/yards to your present antenna supports? How would your neighbors feel about a fairly tall pole supporting a bird house? (And naturally, you would want to guy that pole to keep the bird house from falling, right?) Several possibilities there!

The conductor used for an antenna must be conductive with a low resistive value. After that, almost anything will work (just fine, in most cases). Who wouldn't want gold/silver conductors if po$$ible, but copper works well for us poorer people ;).

If whatever you end up with works, it not being one of the classical 'shapes' for an antenna isn't exactly a "biggy". Having lived in places that were not the 'ideal' antenna sites for most of my life, when confronted with a site that could hold almost any antenna, I was really at a loss as to what to do. And since the antennas I have used prior to that were never 'ideal', I ended up using one of those "less than ideal" antennas and did just fine. Did I have the 'best' signal on the band? Not exactly! But so what, it was "good enough". I think you are in about the same situation, sort of. (I also do not have a planning commission or deed restrictions to worry about, so guess I'm 'ahead' of you in that regard.)
Good luck!
- 'Doc

(Pssst! Put that tuner on the roof, cover with something that looks like a "sun roof" thingy, support the antenna wire with a post with a weather vane on the top. If questioned, say the @#$ thing has been there for ages, those @#$ - ^%%^ neighbors don't know what they are talking about!)

4444. Grounding Possibilities

Newsgroup: rec.radio.amateur.antenna

I live in a 1 story home with a accessible attic.

I have an Icom AH-4 tuner mounted in the attic, and need to run a real ground to the 8' ground rod we just pounded in.

My question is - should the ground wire coming from the AH-4 be of a wire gauge of #12, or should I consider running 1/4" copper tubing? The total length of the run is approximately 30'

73's

4445. Use of type 31 ferrite as coax common mode choke

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-21 14:21:36 UTC
From: "J. Mc Laughlin" <jcm@power-net.net>
Message-ID: <RtydnRDA8Y1wP5HVnZ2dnUVZ_gWdnZ2d@bright.net>
Source record: 25867

I looked through saved messages and the only reference to type 31 ferrite (Fair-Rite) was in March of 2005. That reference had to do with ignition wires.

Recommendations for HF choking ferrites have centered on the 70 series with type 43 being favorably recommended for the upper portion of HF and VHF. However, Fair-Rite seems to be recommending type 31 for HF. See Figure 26 in:
http://www.fair-rite.com/newfair/pdf/CUP%20Paper.pdf

Am I missing something? It seems to me that for the purpose of choking common mode current (on the outside of the outer conductor of coax) from 3 to 25 MHz one should prefer the use of type 31. This is a receiving application with a long run of coax.

73, Mac N8TT

P.S. I will also appreciate ideas about places to purchase ferrite in addition to Mouser.

==========
That 30 ft run ,whether wire or tubing could possibly radiate RF ,hence
it might be better to have an artificial ground (a series resonant tuned
circuit + a length of insulated wire) located on the loft .
The unit is tuned for maximum current .

Such a unit can be easily homebrewed ,however it can also be purchased
from MFJ (their model MFJ-931) , be it that it is to be locally
operated which might be a problem when the Icom AH-4 tuner is remotely
operated away from the loft.

Thank you Bryan - now I know that a lot of the interesting stuff in
the Daburn catalog can be ordered from Davis RF, and that satisfies
almost all my wants and desires. Thanks so so much for pointing that
out, as well as the immediate relation between the Davis catalog and
the Daburn part numbers!

The Daburn 10-52 (also in the Davis RF catalog) is a very very
impressive feedthrough - I'm very happy to see it mentioned,
available, and at an affordable price!

No, I can quit wasting my time thinking about it
because "we do not care". We not caring takes away
any reason or purpose for continuing the discussion.

> With an ideal voltage source being capable of removing
> energy, it should no longer be necessary for you to
> propose strange notions of energy flowing through an
> ideal voltage source and bouncing off the ground.

The discussion is moot unless you can prove that an
ideal source in a single-source system can absorb
AVERAGE power. So there's your challenge. If you
cannot do that, my article about average power
stands as written.

That's the first time you have used the word "remove".
Have you changed your mind about energy being "absorbed",
by the source, i.e. turned into heat?

> Dissipate is not a good choice since it usually implies
> conversion to heat.

Whoa there Keith, "absorb" is equally not a good choice
since it usually implies conversion to heat as in the IEEE
definitions. If the source only removes energy, then that
is a plus for my side of the argument. If the source has
the ability to remove the destructive interference and
supply it back 90 degrees later as constructive interference,
the entire mystery of where the reflected power goes is
solved. When I previously offered that as a solution, you
turned it down flat. Now you seem to be agreeing with it.

> Absorb is not a good word for you, since you can find absorption
> in the IEEE dictionary and it also suggests conversion to heat.

That's why I have been arguing loud and long against the
absorption of energy by the source. It would imply that
the source is heating up or has an infinite ability to
"irreversibly convert the energy of an EM wave into another
form of energy". That irreversible energy conversion is
what I have been objecting to. There is no way an impedance
of 0+j0 can cause an irreversible energy conversion.

> A word that gives no hint about where this energy goes would
> be best, ...

So you can sweep it under the rug and "not care where it
went"? As I said, further discussion is pointless. You
have a magic source that obeys your every whim. Why didn't
you just say that in the first place?

Hi Mac,

I can't say that I have any familiarity with type 31, but certainly
the rest and others. My reference is a 13 year old hard-copy that
does not have this material listed, so it is hard to make side-by-side
comparisons for like-sized beads. Looking at the other charts it
would seem that type 31 would have less "bulk" Z (it would take more
beads at any particular frequency to equal other formulations).

As for your application, and if it is a particularly long run along
ground, or underground, ground itself may provide sufficient snubbing
of Common Mode currents. Except, of course, 60Hz which could be
particularly vicious and I would recommend running a parallel bare
ground wire to the remote ground. In that regard, you may even need
tri-ax.

Are you running that ground for RF reasons, or electrical safety reasons? For instance, are you using it to match a dipole style antenna or a vertical?

Is the antenna inside or outside?

For electrical safety, the coax shield will probably meet the NEC requirements (assuming you've got the appropriate "shield to electrical safety ground" connection at the bottom). And, if the antenna is entirely inside, there's no issue with the NEC anyway.

From an RF resistance standpoint, the resistance difference between 1/4" copper tubing (3/8" OD (.375")) and AWG #12 (about 0.081 inch diameter) is about 1:5 (skin effect means that you're really concerned about circumference, rather than area). If you're interested in reducing the RF resistance, using the shield of a piece of coax might be better (i.e. it's larger in diameter, and the center isn't carrying any current anyway).. But even for the AWG12, the resistance is pretty low (sub 1 ohm for your 30 foot run)

From a RF impedance standpoint, the inductance is a bigger problem. That 30 feet is about 10 microhenries, not to mention that it is probably a good fraction of a wavelength or more.

Fair-rite 31 mix is a new one specifically developed for RF choking applications. As you mention, it has a huge range of frequencies for which it's useful. The recommendations one sees in older literature for 73, 43, etc, were formulated back before the new mix was available. Of course, once something is written, it gets copied over and over without a lot of thought being put into whether the underlying assumptions are still met: in this case, what mixes are available.

Page 888 in the Mouser catalog shows some 31 mix parts..
http://www.mouser.com/catalog/633/888.pdf

You can also go to Fair-rite's website and find a list of their local distributors (Lodestone Pacific, for instance).

The 3&4 digits of the part number are the mix:

xx31yyyyyyy is a 31 mix part.

I don't know about that... the 31 material is around mu=300-800 in the HF area, which is higher than the venerable 43, and a lot higher than the 61.

Another advantage of the 31 material is better performance at higher temperatures.

K9YC has written up a 50 odd page handbook on RFI suppression, choking, etc., with a whole raft of test data on actual chokes (bead baluns, toroids, etc.) made of various materials.

Dear Richard:

Oh my! It appears that you need a new reference. One may order a catalog
from the Fair-Rite site.

Your comment about the effect of ground is useful. However, the direction
of the coax run is such that it could enhance the vertically polarized (E
vector normal to the earth) wave received by the receiving antenna. This
might partially defeat the utility of a receiving antenna distant from noise
sources. I will test that hypothesis with NEC4.

Dear Jim: Thanks for the handbook reference. I can not remember if I have looked at it or not, but I sure will do so.

Your material references are more recent than those of Richard. Warm regards, Mac N8TT

Dear Jim:

Now I begin to see light. While type 31 must be at least three years old,
the world has not yet caught up to its existence.

Thanks also for the hints. Warm regards, Mac N8TT

4463. SG-230 problem

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-21 20:46:53 UTC
From: Andy <dx90@blueyounder.co.uk>
Message-ID: <V27Pj.102710$Lq5.16290@newsfe18.ams2>
Source record: 25885

Hi all

I purchased the SG-230 about 4 years ago. I took it out of its box yesterday for the first time and tested it out on a light bulb as a dummy load and all worked fine. It found a match on all HF bands.
I connected it to an antenna today and it would not tune. It would not reset with the Smartlock. I took the back off the 230 and noticed when I apply the 13.8 Volts all the relays click once and they
all stay in that position until I disconnect the power and if I apply RF, 10-80 watts when the 230 is powered up it does nothing, it doesn't even attempt to tune.. I have also tried 2 lengths of 10ft wire and it does nothing.
There are five LED's inside that are all on (green).

Does anyone know what is causing this problem?

73 Andy

the *amateur* world hasn't caught up.. I haven't looked, but I'd venture that the ARRL handbook still doesn't mention it (if only because it would be a expensive and herculean task to revise the entire handbook every year). And, folks writing in QST tend not to be in the business, so they're using what they learned in the handbook.

For instance, the RFI/EMC page on the arrl web site says:
"Original text reprinted from February and March 1992 QST "Lab Notes" columns Copyright ï¿½ 1992 by the American Radio Relay League, Inc. All rights reserved."

"Or, you can make a common-mode choke by wrapping 10 to 20 turns of the antenna feed line or CATV cable through a ferrite toroid. Follow the same procedure with the ac line. Use #75 (also known as "J"), #73 or #77 material if the interference is mainly from signals below 10 MHz. Use #43 ferrite material for the higher bands or low VHF."

"To make a ferrite common-mode choke, wrap 5-10 turns of a conductor onto an FT-240-43 ferrite core. (The "240" indicates that the outer diameter of the core is 2.4"; the "43" designates the material. Other materials may be useful, but 43 is a good all-around material.)"

(to be fair, they do link to K9YC's writeup)

Dear Jim: Thank you.

I had read an early version of K9YC's work. It was informative to read the
latest version. He does a good job.

It appears that my question may have had a positive effect and
radio-amateurs will consider type 31 for HF.

A fairly brief look at the graphs (Figs. 6 - 8) shows that type 31 has roughly the same or a little higher total complex permeability than 73 over most of the lower HF range and same or higher than 43 on up to 100 MHz. So it should be a good ferrite to use for very wide band applications. However, Table 1 shows that it's available in large parts only. Type 43 is very widely available in a wide variety of sizes, so you might have a lot more luck getting cores of the sizes you need in type 43.

You might try Amidon (https://www.amidoncorp.com/) or the Wire Man (http://thewireman.com/baluns.html#901). I don't think I've bought anything from Amidon since Bill Amidon sold it, but see their brand on small quantities of cores at the local electronics shop. Press Jones, the Wire Man, is great to do business with.

> in real life.

EZNEC isn't able to model some radiating lines. If you use the transmission line model, the line doesn't radiate. If you model it with wires to allow radiation, you can use the wire insulation feature to simulate a thin layer of insulation on the wires. This will have a small (typically 2 - 3%) effect on the effective length of the wires as far as common mode currents go, but very little effect on the differential (transmission line) operation. But there's no way to model insulation between wires, so when it has a significant effect on operation, the analysis won't be accurate. Sometimes it's possible to separately model the common and differential mode characteristics. For example, a folded dipole can be modeled as a conventional dipole (for the common mode) with transmission line model stubs across the feedpoint (representing the differential, or transmission line mode) and a transformer for the impedance transformation. Or a coax can be modeled as described in the EZNEC manual. But in many cases, building such a model is difficult at best. However, you can often get a good idea of how a system will work, even if the actual antenna will require some adjustment compared to the model.

Amidon do stock some type 31 products, including FT-240-31 toroids and
the large beads for RG213, but they aren't listed on the website.

Part numbering is the same as normal, so simply substitute a "31" in the
part number you wish to order, and then call 1-800-898-1883.

Mac,

Whilst playing around with models of a Guanella balun, I did compare #31 sleeves with Walt's design using #73 sleeves over the range 1 - 30MHz.

My model of Walt's balun is at http://www.vk1od.net/balun/W2DU/index.htm . I obtained different results to Walt's measurements, but I think that is because Walt's measurements were affected by stray capacitance that was worse than would apply to that type of balun in service.

I also modelled some Fair-rite 2631480002 sleeves and found a slightly longer choke (12 cores at 25.4mm ea) was needed to achieve about the same choking impedance up to about 12MHz, above which the #31 choke had higher impedance than the #73 one.

Whilst I modelled these sleeves because they suited the application, I have not seen anyone selling them in small quantities.

Owen

The best analogy I can think of is someone saying:
"Until you prove the earth is flat, I will not consider
any evidence that it is round".

Another question remains, since it is difficult to
discern from your writings: Have you grasped the
behaviour of an ideal voltage source when current
is flowing into the source?

You now understand that it removes energy from the
circuit?

If you have that for DC ideal voltage sources, we
can move on to discover what happens with AC ideal
voltage sources. After that, we can go back to what
is happening in your circuit.

You need to read more carefully. Not the first time at all.

> Have you changed your mind about energy being "absorbed",
> by the source, i.e. turned into heat?

What I have said is that an ideal voltage source removes energy
from a circuit and that we do not know what it does with the
energy it removes. In practice, devices which are designed to
approximate ideal voltage sources do simply dissipate the energy
they remove from the circuit.

But that is not part of the definition of an ideal voltage source,
for which no statement about where the energy removed goes is
made.

> turned it down flat. Now you seem to be agreeing with it.

No. We do not know what an ideal voltage source does with
energy it removes. We can not say that it stores and then
returns it, though a particular implementation might do
so. Another implementation might not. So this can not be
used as an explanation.

> > Absorb is not a good word for you, since you can find absorption

> of 0+j0 can cause an irreversible energy conversion.

I am sorry that the occasional use of the word 'absorb' so
mislead you. I avoided 'dissipate' for that reason. It is
not so obvious why you were mislead by the use of 'remove'.

> > A word that gives no hint about where this energy goes would
> > be best, ...
>
> So you can sweep it under the rug and "not care where it
> went"?

No. Because the definition of an ideal voltage does not specify
where the energy goes. Therefore we had better not care when
we use an ideal voltage source.

> As I said, further discussion is pointless. You
> have a magic source that obeys your every whim. Why didn't
> you just say that in the first place?

No. My ideal voltage source just obeys the definition of an
ideal voltage source. It provides energy to the circuit when
the circuit conditions demand that it do so and similarly it
removes energy when the circuit conditions demand that it do
so. The definition does not tell us where the energy it
provides comes from, nor does it tell us where the energy
it removes goes.

A fairly simple defintion: The voltage at the terminals is
maintained at the desired value, regardless of the current
flow needed to do so.

No magic in the definition whatsoever. And no need to obey
whims.

I have repaired mine a couple of times. The SGC documentation
is very good. Have you checked the four lines between the
Smartlock and the SGC-230? If the notune line (white wire)
is at ground, the tuner is in perpetual reset. The notune
line should be at a plus voltage when the reset button
is not pushed and go to ground when the reset button is
pushed. The digital control portion of the tuner is super
easy to troubleshoot and a good technician should be able
to diagnose and repair minor problems. All of my problems
have been minor and easy to repair.

The most nagging problem was when the tuner wouldn't tune
while my pickup was in motion but would tune just as soon
as I stopped the vehicle. It was a loose nut inside
the box on the output feedthrough insulator.

Have you tried the tuner without Smartlock in the circuit?

It follows that it is futile to try to track any
movement of instantaneous energy. You have convinced
me that you are correct - "We don't care where the
(instantaneous) energy goes."

> If you have that for DC ideal voltage sources, we
> can move on to discover what happens with AC ideal
> voltage sources. After that, we can go back to what
> is happening in your circuit.

Since there is an instantaneous leak in the closed
system, it is useless to proceed. You say you don't
care what happens to the energy. I said a couple of
months ago that I didn't care what happens to
instantaneous power. And indeed, you have convinced
me that any attempt to track instantaneous power is
doomed to failure.

My part 1 article based on a single source and
AVERAGE powers doesn't have those conceptual
problems and stands as written. Here's the second
paragraph from that article:

"Please note that any power referred to in this paper
is an AVERAGE POWER. Instantaneous power is beyond the
scope of this article, irrelevant to the following
discussion, and "of limited utility" according to
Eugene Hecht. [4]

Your challenge is to prove that a single source
removes an average amount of energy from the
network.

Sorry, you specifically said that an ideal voltage source
"absorbs" energy, i.e. irreversibly converts energy to
another form, the most common form of which is heat.

> I am sorry that the occasional use of the word 'absorb' so
> mislead you. I avoided 'dissipate' for that reason.

The IEEE Dictionary says that, in this context, "absorb"
and "dissipate" are virtual synonyms.

Just doubled checked without the Smartlock connected. No change. I did
notice that the braid of the coax where it connects to the terminal inside
had broke off. Re-soldered this and its still the same. This was due to the
big plastic nut on the back being lose and allowing the cable to turn.
I wish I could fix it myself. But I would have to be talked through how to
check the components to see if they were ok or not.

I think the type 31 is entended for use on things like power cords and
computer cables to prevent unwanted radiation/pickup of RF. Im not
sure how well it would meet your requirements but I suspect it may be
OK in a receive only situation. I have tried using some unknown types
of cores removed from various computer cables for a balun and the
vinyl tape holding them to the coax got very soft when they heated up.
Perhaps some experimentation using these cores is in order.

Apparently this testing has already been done.
Just google "type 31 ferrite" for results.

Verify there's a good RF ground connected to the tuner.
Even if you're using some kind of balanced antenna,
my tuners are happier with a little metal on the ground.
I have a simple, 12' piece of braid bolted to the
tuner/transciever cases and simply laying on the sand.

Unfortunately I don't know anyone.
I have been off the air for a long time. After the move to here and having very good neighbours I am able to get back on the air. Well until the tuner stopped working.

I did find this PDF doc just now. I have the model after the year 2000.

Barrett wrote:
> Does it have to be a T shape and why?...

It "has to be" a piece of metal in the air.
That's about the only constraint. And seeing as
there are underground antennas, that constraint
is not always constant.

Put metal in the air. Tune it up. Work the world.

I'm on 20 and 40 meters on 5 watts on a
~75' dipole through a tuner every day. I make
contacts with Austraila, S America, Euro, Hawaii,
all from my little remote QRP SSB station in Arizona.
My dipole isn't tuned. It's simply two halves of a 150'
piece of wire I had.

I've done the same thing on a 35' wire, a ham stick
vert and a pair of hamsticks horizontal. I've loaded
up an aluminum lawn chair and worked Canada and the
USA midwest, Florida, New England. The difference
in any of the signals received is perhaps a couple
of dB.

Source record: 25813

Greetings All,

Saw the posts about Mix 31 ferrites, which I use on my mobile installations with good luck, using HiQ 5/160 antenna and Icom IC7000. If anyone is interested, I recently posted on my web site a document the describes the installation of ferrites for HF installations. This is based on what has worked for me, information from Fair Rite's web site, and ideas from various past posings. Also listed is a partial list of suppliers - as always check the prices as they can vary a lot!

Check it out and let me know (direct email) if you have any other suggestions and if you find this useful, as this is meant to be a "continous improvement" document. I also plan to write additional guidelines as time permits: www.repdesign.us , go to the "Downloads" page (left side of screen towards the bottom), and go to the third group to download or simply open to read the PDF document.

73,
Dick Post, N7EMW

Large, in this context, isn't all that big. You can't get it in tiny ferrite beads to slip over a AWG30 wire. You can get it in 0.485" OD 0.5" long beads with a 0.2" hole in the middle.... $0.42 each from Mouser. Similar snap on cases too..

Small, for Fair-rite, means things like those little 1/4" diameter multi hole cores for making wound EMI filters, or chip components.

I buy it in 2.4" toroids so I can put multiple turns of coax on.

Mouser has them.. Don't know if they ship in VK land or not. Shipping
of what is basically iron bars is going to be punitive. FairRite has
distribution there (Specialised Conductives in Victoria), but perhaps
not retail. But, since one typically isn't looking to buy just one, but
dozens, this might not be a problem.

One should be careful about modeling these things.. that gets you close,
but parasitics are a real bugabear. K9YC's paper has actual
measurements on actual chokes made with a variety of cores (which are
decidedly non-trivial to make..)

Snelling's book is the tome of choice, if you can find it...

#31 is specifically made for our kind of application (transmitting).. it has a higher temperature rating than the other popular materials. The key on managing dissipation is making sure you have enough impedance so that the current is small.

It's a long way from the miscellaneous stuff used for RFI on power cords and keyboards..

This place has 59 different style standoffs and insulators, mostly
plastic, some
interesting mounts.

This one is porcelain with lag screw.

http://www.farmsupplystore.com/departments/special-insulators/large-porcelain-insulator

And then the whole list of 59.

The following is a copy of my message posted earlier to the general group, but I had wanted to preply directly to this topic as it's very pertinent to the discussion of ferrites, so here is the message again (sorry if you see this twice).

Greetings All,

Saw the posts about Mix 31 ferrites, which I use on my mobile installations with good results, using a HiQ 5/160 antenna and Icom IC7000.
If anyone is interested, I recently posted on my web site a document the describes the installation of ferrites for HF installations: : www.repdesign.us ,
(go to the "Downloads" page (left side of screen towards the bottom), and go to the third group to download or simply open to read the PDF document).

This is based on what has worked well for me, information from Fair Rite's web
site, and ideas from various past posings. Also listed is a partial list of suppliers - as always check the prices as they can vary a lot!

Check it out and let me know (direct email) if you have any other suggestions and if you find this useful, as this is meant to be a "continous improvement" document. I also plan to write additional guidelines as time permits.

73,
Dick Post, N7EMW
www.repdesign.us

For some reason, magnetics ex USA through Aussie distributors / retailers
are outrageously expensive. Typically on Ebay one can buy 10 cores ex USA
for the price of one from a Aussie retailer.

> One should be careful about modeling these things.. that gets you
> close, but parasitics are a real bugabear. K9YC's paper has actual

Yes, agreed. I have made measurements of a number of choke
configurations, albeit only with a TAPR VNA (hate the software), and
calibrated my models to the measured values. It is certainly a balancing
act to put enough turns on a toroid to get high Z, but few enough turns
that Z hasn't gone seriously south at the top end of the desired range.

Predicting magnetics behaviour is a bit of a black art, but models help
to guide one to a better understanding of behaviour.

It is little wonder than balun specifications, where they are given, bear
little relation to the intended application.

I never met him but he was one of my Elmers anyway.

73 de Jim, N2EY

More detail, forwarded from another group:

quoting Mr. Stone:

Folks:

This is the saddest announcement we have had to make:

It was discovered this morning that LB Cebik, W4RNL
had passed away.

He was a friend to us all and will leave behind
a great void. His beloved wife, Jean passed several
years before and he missed her greatly.

He was my friend and associate for 10+ years and I
shall always remember him for his warmth and kindness.

A tribute to this "kind and gentle giant" shall
appear in my column in the next issue of antenneX.

Dear Roy: The use of small and large in this context is not clear. So far, I have found the sizes of type 31 to be about the right size. On the other hand, some of the 7X types seem only to be available in sizes that are too small.

Your point that the type, and its performance, is only part of the issue. One must also have parts that fit.

Thanks, Mac N8TT

Dear Owen: Stray capacitance due to more than one source has a big effect.
Your getting similar results with a few more 31 types than 73 types is
certainly above the noise level and reinforces the utility of 31.

Thanks. 73, Mac N8TT

The wordy non-sequitor leaves us with nagging doubts about
whether the fundamentals of DC ideal voltage sources have
been grasped.

But since the whole work is predicated on a misunderstanding
of the behaviour of ideal voltage sources, any conclusions
retain no value.

I did use the word 'absorb' to convey the concept of removing
energy from a circuit without knowing where the energy went.
You misinterpreted my use of 'absorb' to mean something else.

These things happen. Most readers, upon learning the intended
meaning of a word was different than expected, would simply
re-read the affected passages to glean the intended meaning.

This seems difficult for you. May I suggest that substituting
'remove' for 'absorb' might help you gain an understanding
of the intent.

Don't worry. Knowing your difficulty with detecting the
intended meaning of words, in future I shall avoid 'absorb'
when I mean "removing energy from a circuit without knowing
where the energy goes."

With your difficulty using the word 'absorb' to represent the
abstract concept of removing energy without knowing where it
goes, for a better understanding please re-read these passages
substituting 'remove' for 'absorb'.

> >> When it is sinking current, it is *absorbing* energy.

It certainly is one of the many possible things that might
happen to the energy that is removed. As I wrote previously,
"In practice, devices which are designed to approximate
ideal voltage sources do simply dissipate the energy they
remove from the circuit."

Still, since we do not *know* what happens to the energy removed
by an ideal voltage source, we can make no assumptions.

I have 3 snapshots, 2 likely complete from 06 and 07, and one I just tried this evening. Antennex is blocking site duplications a bit, plus the site is slightly broken, which make a snapshot no longer possible, at least easily.

So, summarizing, I have a probably good snapshot from about a year ago, one probably good from about 2 years ago, and one from today that is maybe 15% complete.

Hello, all, and it is always sad when another silent key is added. I
don't make a habit of reading articles posted on antennex.com since it was
they who were (still are?) backers of the CFA and other flawed (IMO)
concepts. (I was surprised some years back when antennex.com published
Dr. John (Jack) Belrose's mythbusting paper on the CFA using the results
of a NEC model of that antenna.)
No doubt antennex.com also has promulgated some viable antenna designs.
Now, if non-engineers/non-physicists would just refrain from trying to
explain the underlying "theory" of operation behind their revolutionary
spare-time antenna designs. Please excuse the rant and I don't mean to
imply that W4RNL contributed to any of this. My best to W4RNL's family.
Sincerely, and 73's from N4GGO,

Well, let's try one more time and see. Assuming a 50 ohm
environment (by definition) in the following example, what
will an ideal 50 ohm directional wattmeter indicate at
point 'x' for forward power (Pf1) and reverse power (Pr1)?

```
Pf1--> 50 ohm Pf2=50w-->
+----x-----/\/\/\/\-------45 deg 50 ohm-----short
| <--Pr1 Rs <--Pr2=50w
| 100w
Vs=100v
|
Gnd
```

It's a simple question with easily calculated and
quantifiable answers.

Your circuit is incomplete. The circuit parameters are not fully defined.

Is this the same circuit that you wish to analyze?

```
Pf1--> 50 ohm Pf2=50w-->
+----x-----/\/\/\/\-------45 deg 50 ohm-----+
| <--Pr1 Rs <--Pr2=50w |
| 100w |
Vs=100v |
| |
Gnd Gnd
```

What is the impedance of the voltage delivered from Vs before the wave encounters the resistor Rs?

What reflection characteristics should we assume for the voltage source Vs?

The coax is shorted at the end, and Gnd is 45
degrees away from the short.

> What is the impedance of the voltage delivered from Vs before the wave encounters the resistor Rs?

Assume that Rs is 100% of the source impedance.

> What reflection characteristics should we assume for the voltage source Vs?

Assuming that Rs is 100% of the source impedance
should answer that question.

Is this a standard ideal voltage source which provides energy
to the circuit when the product of its voltage and current is
positive and removes energy from the circuit when the product
of its voltage and current is negative?

Or have you assigned it some other non-standard definition?

Amidon is sort of on-again/off-again when it comes to supporting the retail ham market. Sometimes they are pretty good, but other times they're just terrible. Might have something to do with changes in ownership and management over the years, or just whether they get busy with bread and butter commerical customers. They've also used a wide variety of suppliers over the years.

And the whole Amidon, Amidon Associates, Applied Magnetics, BTC Power Electronics, Flat Transformer Technology, thing...

It's been a long time since Bill Amidon ran it from his garage in North Hollywood providing retail distribution for Fair-Rite and Micrometals products.

Wow, that was fast.
Antennex now requires registration (free) to access the cebik.com site.
I wonder how many thousand websites now contain broken reference links.

You should use this system if you are traveling and not in a familiar area
to do your reporting.

73's
USA Skywarn
National Toll Free Number Update
The National Weather Service National Toll Free Severe Weather Hotline is
now up and operational.
NATIONAL SEVERE WEATHER REPORTING HOTLINE 877-633-6772

The National Weather Service encourages everyone to report severe weather.

TO REPORT SEVERE WEATHER,

To Use This System you Need to Have Either your,

1: Latitude Longitude by Degrees and Minutes

2: Or Zip Code

If either of these two items are not available then you must leave a very
detailed voice message as to your location at the end of the call such as
nearest:

City, County, & State

Nearest Cross Streets

Land Marks Highway Mile Markers Etc....

SEVERE WEATHER REPORTING BASIC GUIDE LINES

1: TORNADO: A violently rotating column of air in contact with the ground
and extending from the base of a thunderstorm.

2: FUNNEL CLOUD: Violently rotating column of air that is not in contact
with the ground.

3: HAIL: Penny sized hail or larger.

4: DAMAGING WINDS: Trees/power lines knocked down, damage to homes, etc. If
you have an anemometer, report any sustained winds over 45 or
gusts over 58 mph. (Note: sustained winds are a one minute average.)

4a: High Winds: Wind gusts in excess of 58 mph. (Large Limbs or Trees Down
Wide Spread Damage)

5: Flash flooding.

6: Weather Related Damage to structures, buildings, barns, or cars and trees.

7: SNOW: One inch accumulation or more in three hours. 4 inches in 12 hours or less.

8: FREEZING PRECIPITATION: Any accumulation of sleet or freezing rain/drizzle.

9: POOR VISIBILITY: Reduced visibility adversely impacting transportation. Less than one-half miles for: BLOWING DUST and VOLCANIC ASH. Less than 1/4 Mile for: DENSE FOG and BLOWING SNOW.

When Prompted to leave a Voice Message:

Be as descriptive as possible, rainfall amounts and any damage or weather occurrence you feel is important to report.

I am not surprised.

Antennax are commercial publishers, and they are the publishers of
cebik.com .

Whilst Cebik implored people to not bulk copy his site, he did offer the
option of a $35 CD from Antennax. The site contained measured to prevent
certain kinds of access. No doubt Antennax's action is to protect their
revenue stream.

I am sure that many publishers will be revising their websites to remove
links to Antennax's archived / restricted cebik.com site.

Source record: 25710

Hi to all,

Until now, I used a 4:1 Van Gorden Balun with an OCF dipole and of course a coax line to the tuner. I am now trying a 450 Window ladder line. For now, the antenna is still connected to the balun, but I removed the coax from it, and I use the balanced line connector of my MFJ-949E antenna tuner (a 4:1 balun is in that tuner).

My question: Should I remove the old balun or may I keep it, i.e. does it has any influence even if the coax is removed?

I find it convenient since the balun is a good holder for the antenna's two branches.

Mac, If you have your heart set on #31 mix, this option isn't a good one... but if you can use #73 or #43, you will regularly see sleeves in various sizes and materials on Ebay. Many have Fair-rite numbers so you can check to see if they suit.

Some advertisers state that the cores are Fair-rite cores, if they know that, they should know the part numbers though they don't always state them in the descriptions.

I have bought ferrites from one of the suppliers, the goods seem to comply with the part number descriptions (dimensions, mu) and their service to Australia was quick and cheap.

In this part of the world, product from Asia is available economically... but we have to characterise them and long term product availability is a bit of an issue.

Am putting up a tower, 60', and was wondering if there is any issues with
the following arrangement:

On top and working down to the tower top section...

1) HF Beam Antenna, then
2) 2 Meter Beam Antenna, then
3) Dipole for 40, 80, 160 M, then
4) Directional HDTV antenna, all on the mast, all turned via rotor.

Any problems with this arrangement?

Glenn

> Any problems with this arrangement?

I think the usual practice is to put the VHF/UHF antennas
on top of the HF beam so that they don't have to "look through"
that larger metal structure and perhaps have their patterns
disrupted by it. Also, I see problems rotating the 40/80/160
dipole ;-)

Source record: 25716

Hi Andy,

I had a similar problem with my SG-231. It turned out to be a corrosion problem in the power/control connector. This made a electrical connection to be made to the Reset/Hold/Tune leads. There was a little corrosion on the back side of the circuit board as well. Look up into the male connector and disassemble the female.

I cleaned up the corrosion problems with a dental pick and fine wire brush. I resealed the connectors with epoxy. The silicon sealant SGC used seems to be effected by moisture as it had become milky looking till it dried out.

Hope this helps.

Chris

Glenn,
There shouldn't be any more (or less) interference between the HDTV antenna and the others than there would be for a 'regular' TV antenna. As with either type of TV antenna, distance from things around them will directly affect how much they may be affected by the 'other' antennas simply being there. That says nothing about whether the ham antennas are in use at the time! (Kind'a figured that anyway, huh?)
- 'Doc

4546. Re: Balun question

Source record: 25718

Pierre,
If you don't remove that 'old' balun, then you don't have a 4:1 conversion anymore, but with 'both' baluns connected, it's more on the order of an 8:1 conversion. Is that 'bad'? That depends on the antenna's impedance and the feed line's impedance, but in general, I would think that it wouldn't exactly be the 'best' thing you could do. Removing the 'old' balun would probably be your 'best' bet. May make making connections a little more difficult (or at least 'different') but still the 'best' solution.
Then again, before doing that "out with the old" thingy, try it and see what the results are with both baluns in-line. Results 'better' with or without the old balun still in line? Hmm, if I had to 'guess', I'd have to say removing the old balun would probably be your best bet. At the very least, it means a little less weight hanging on the antenna, one less 'point of loss' in the whole thing...
- 'Doc

(May not be the 'best' answer in the world, but it's sure a nice "CYA"... ain't it?;))

4547. Re: Balun question

Source record: 25719

... Uhh. May have mis-read your post. If that old balun is only being used as a center insulator, not 'in-line' with the ladder-line, then while it will still be providing some sort of 'impedance bump' because it's too close to the ladder-line, it shouldn't be doing any impedance transforming (the 4:1 thingy to an 8:1 thingy).
Objectionable? Beats me, but probably, too many "depends" in that for a good guess.
- 'Doc

PS - Leaving it-line, but not really doing anything, DOES open the field for all kinds of 'reasons why it's there' when explaining the set up to an interested observer! Can you imagine the B.S. you could invent for that??

Chris,
I will have a look, but its unlikely to be corrosion due to it being stored in its box in my cupboard for the lat 4 years. But it might help others.

This might help you though. Some one did tell me once to seal the SG-230 with silica gel after putting some silica gel in side so soak up any moister. Its those little packets you get inside the box with new electrical items.

Thanks

Keith Dysart wrote:
> Is this a standard ideal voltage source ...

Let's save that discussion for later by dropping
Vs out of the example. The specific characteristics
of the source need not be known for the following
subset problem which, I believe, is the source of
our disagreement, having nothing to do with Vs.
In fact, Vs can be located one wavelength away from
Rs and steady-state conditions will be the same.
Let's take a close look at what is happening only
on each side of Rs in this previous example.

```
100v Vg
Gnd---Vs--x--Rs--+----45deg-50ohm---------short
```

The following are given:

A 100% 50 ohm environment by definition.
Reference Voltage = 100v RMS at point 'x'
Rho = 0.4472 @ 63.4 deg at point 'x'

Rho^2 = 0.2 and an ideal 50 ohm directional wattmeter
will provide the following indications.

```
100v Rs=50ohms Vg
------------x---/\/\/\/\/---+--------------
Pf1=125w--> Prs=100w Pf2=50w-->
<--Pr1=25w <--Pr2=50w
```

These are the energy components that you say do not
balance. But I didn't see Pf1(t) or Pr1(t) in any
of your previous equations. I suggest you will
discover that the destructive interference on one
side of Rs is exactly balanced by the constructive
interference on the other side.

It is unclear where you have connected your ladder-
line at the antenna end. Is it connected through the
coax connector or does it bypass the balun and connect
directly to the antenna wire, i.e. are you trying to
use the old balun as your center insulator?

This is what I intended to do, using the 'eyelets' on the balun to hold each leg and to connect the ladder line to them. Purely a mechanical solution.

But since there is a 0 ohms (DC) resistance between the two posts on the balun, I am concerned abour adverse effects.

4553. 20m 1/4 wave portable vertical

Hi all,

Harbor Freight has a new item currently on sale, a telescoping aluminum flag pole, item 92901. It extends to 16 feet, and can be locked at any arbitrary shorter length down to the 62 inch collapsed length. The bottom section is 2 inches diameter and the fourth, top section is 1.5 inches diameter, so it's easily self-supporting if you have a way to secure the base. It's about 6 pounds. There's a top ball that screws in, so there's a very easy place to add a little plate for a place to attach guys. I haven't had mine long enough to try it, but I expect it will make a fine 20meter-and-above 1/4 wave vertical for portable use. With a bit of capacitive hat and a loading coil, it may even work well on 40m. If you get one, be sure that all the sections lock properly--mine may get exchanged because one of the sections doesn't seem to want to lock.

Cheers,
Tom

You need to measure those impedances at the frequencies of
interest. If the antenna feedpoint impedance is much, much
lower than the impedance looking back into the old balun,
you don't have anything to worry about. You can determine
those impedances with a lot of time and effort. Or you can
remove the balun and install an insulator. Personally, I
would install the free insulator out of my junk box. :-)

That's less expensive than MFJ's 12 foot telescopic
whip and probably lots more sturdy. Have you checked
for continuity between the anodized aluminum sections?

Although this tread is ongoing for some time I respond to the original posting.

If an Off Centre Fed Dipole is directly connected to a twin wire feeder ,be it ladder line or 300 or 450 Ohms twin feeder (please note I do not use the wording : balanced feeder) the current /voltage in the 2 wires at any point on the feeder will not be the same in magnitude and differ 180 degrees in phase ,hence IMHO the feeder will radiate, which should be avoided

If a symmetrical dipole is used there is a reasonable chance that the feeder will NOT radiate and if that indeed is the case you can call the feeder balanced. This can be checked for example by placing a (split) toroid type of RF current sensor around the twin feeder (differential current measurement).

So it makes no sense to connect an OCF Dipole directly to a twin feeder .

Dear Owen: Always good to receive your insight.

Were I to deal with Ebay, I would have a dedicated computer and ISP just for that purpose. I am much too much a belt and suspenders person to wish to avail myself of their "bargains." I leave that to those who are younger. You have reinforced my expectation that from VK land it simply might be a necessity to deal with Ebay and to measure materials received from any distant source.

As an extension, a new field proposed at our university is that of a specialized engineer who is able to make the importation of parts from all over the world work. This has become a real field. It is much worse than the three metric systems that existed at the beginning of WW2 (American, Canadian, and English) such that bolts might only engage a few threads before seizing.

Your skepticism about type 31 causes me to revisit my assumptions.

As always, 73 Mac N8TT

To coax via a (voltage)balun (usually 4:1)
The balun being either a ferrite bar or a toroid , wound with 1 bi-filar
winding eg a 2 to 1 (auto)transformer resulting in 4:1 impedance
transformation.

Outside of wanting to point the ham antenna in one direction and the HDTV at another I doubt you will have any noticable problems. Maybe the ham rig getting into the TV set is all.

I have a 60 foot tower with a 432, 144,50 mhz and then a triband on a single mast. The mast is about 20 feet long and 6 feet is in the tower . The antennas are about 5 feet apart.

At the 45 foot level there is an off center fed antenna I use for 80 and 40 meters.

I don't seem to have any porblems with that setup. YOu just put up what you can with what you have to work with and see what hapens. Here is a web site with some pix of the tower.

Barrett, Sorry for the delay,

I have been pretty busy, but I have time tonight to answer this
better.

A picture is worth 1000 words :)

Based on your pictures, I am guessing you live in the apartment at one
end of the g5rv and the other end is at a shed or carport.

At the apartment, I would mount the antenna coupler to the wall, up
high if possible, but if not, as high as possible, even if it is just
above the ground.
Then run a wire from the coupler to near the roof of the apartment
and across to the far end of where the G5RV is. Then run a ground
wire strait down to one of your ground rods. then take any excess
wire and bury it in your garden under the long wire in the air.

You should have fairly good communications on all bands. If for some
reason one of your bands does not properly tune, then start trimming
off the far end of the wire about 1-2 inches at the time. I don't
think you will have that problem, but it should work if you do.

Before you do, make sure all connections are good.

Again, sorry for the delay.

73 for now.

Don't sweat the low center. I just built one a few days ago and it
worked better than any Inv Vee I've built or used. The reason is the
ends are higher than lower as they would be on an inv vee, therefore
the part of the antenna where it exhibits the highest voltage is
highest above ground helping to eliominate ground losses and increase
efficiency.

You're actually fortunate to have such a nice way to mount the
antenna, in these postage-stamp-size city lots we're lucky to be able
to fit an inv vee, which works, but performs barely OK .

Me thinks you're going to truly love it's performance.

It looks like some of the SM 3-pin diodes D10, D9, etc have failed. I was only testing with a 100 watts although it was with a very high SWR at the time

Do I have to go to SGC for the diodes or is there a replacement that I can use instead?

A 4:1 voltage-balun balances the voltages so
with unequal impedances looking in each direction
at the feedpoint, the currents will be unbalanced
causing feedline radiation. That's why the Carolina
"Windom" (sic) has a choke some distance down from
the feedpoint.

So an OCF Dipole seems to have feedline radiation
with either twinlead or coax+voltage-balun. The ARRL
Antenna Book says a 4:1 current-choke-balun will solve
the feedline radiation problem but 4:1 current baluns
usually require two cores.

My SGC-230 manual says those are 1N4148 high speed
switching diodes which are one of the most popular
diodes of all time. They should be readily available
almost anywhere.

Source record: 25758

Your proposal looks upside down to me. The HF beam is normally the largest weight and windload, and would normally go at the bottom of the mast, closest to the rotor. However, you've also listed a rotatable 40/80/160 dipole which must be a huge mechanical monster. If that's accurate, it definitely goes at the bottom of the mast, then the HF beam above, vertically separated by not less than 1/4 wavelength.

The mast needs to be at least 20 feet tall (if the beam starts on 20M), in order to mount the HF beam 16 feet above the rotatable dipole, and then have the 2M beam 20" above the HF beam.

If possible, keep the directional TV antenna far away from all of the above, using a separate support mast and rotor. It's doubtful that your XYL will always want to watch TV stations located in the same general direction that you are working DX. Also, a strong local 2M signal from your beam will probably cause noticeable interference to DTV signals in the VHF Hi TV band (channels 7-13).

Cecil,

I had a look at the 1N4148, they are 2-pin.

The diodes in mine are Surface mount 3-pin.

Are the 1N4148 diodes for the old version board, before year 2000?

My board is the newer version, after year 2000

>My LPDA is too directional.

Well, considering that there really is no such thing as an HDTV antenna per se, yes. HDTV in the U.S. (ATSC) uses a subset of the same frequencies used by ATSC television, and so all the same considerations apply.

The commonest commercial solution to your need seems to take the form of a saucer-shaped radome, containing an amplified near-omnidirectional UHF/VHF antenna. One source is

http://www.starkelectronic.com/allant.htm

Internally, I believe that these consist of a standard or folded dipole, with the elements "swept" into an S shape. They're probably not terribly good antennas, as far as matching or sensitivity or pattern is concerned, which is likely why an onboard amplifier is included.

If you wanted to tune up only one (or a few closely-spaced) HDTV stations with an omni, you could probably build yourself a turnstile antenna... a crossed pair of bow-tie elements, and a 90-degree phasing harness cut for the middle of the band would probably work. I doubt that'll work as a general-purpose solution for the full band, though.

The specific sort of antenna design you might need to work well in your area, will depend a lot on which frequencies are going to be in use for DTV in your area after The Big Day Next Year. In many areas of the country, all TV signals will be in the UHF band - this simplifies matters for residents of those areas, as only a UHF antenna will be needed.

In more crowded areas of the country (and in some locations where the broadcasters don't want to re-fit their main transmitters) DTV will include stations operating in the VHF high band (channels 7-13) and you'll need an antenna which works on these frequencies as well.

In a very few areas, there will still be stations operating DTV in the VHF low band (channels 2-6), and residents of those areas will still need full-coverage antennas.

>Also, is TVI from ham transmitters reduced with
>HDTV?

It depends.

The worst ham TVI problems seem to have affected Channel 2, due to its proximity to the 6-meter band and its second-harmonic relationship to the 10-meter band. There will be *very* few TV stations using this frequency after The Day, and this may reduce TVI complaints for hams operating on 2 and 6 meters.

Strong-signal overload/desense problems of TVs (or antenna/CATV distribution amplifiers) will probably still exist, especially for TV stations operating in the VHF low and high bands. I imagine that high-power ham transmissions in the 70 cm band may cause overload problems for UHF TV stations in some cases.

The actual behavior of the TV sets, in the face of ham TVI, will definitely be different. No more herringbones in the video, no more desense-related snow. Instead, the picture and audio will be unaffected, until the TVI is severe enough that the DTV tuner and demodulator can no longer get enough of a signal to allow the digital error-correction process to work - at that point, the image will start freezing, breaking up into rectangular "macroblock" artifacts, or disappearing entirely. TVI is likely to present as much more of an "all-or-nothing" thing that it did in the past.

> Just wonder how they got on with it.?
>
> Patrick GW1SXN

Just for curiosity I once ran a NEC simulation of the "TAK-tenna" on 7 MHz
at 30 ft
above an average ground. The input impedance at resonance is 3.4 ohms, and
radiation efficiency just under 9%. Using 50 ft of RG-213 the input
impedance
is 5.4 + j 12.4 ohms, and line loss 1.72 dB. Maximum gain, at a 30 degree
take-off
angle, shows -7.7 dbi. Nulls off each end are -14 dbi.

With the above results an input power of 100 W radiates 6 W. I believe they
claim
a low input VSWR. Have no idea how they achieve it without a matching
network.

This is the problem that I have got with my SG-230.
I purchased it new myself. My PCB board is an Q50102000-E. it is what they call the newer version, after the year 2000.

My manual is a Revised: November 2000. The Document number for the schematic, Q30102000E Rev: A Dated February 17, 1992. It looks to me to be the wrong schematic for my PCB board. Maybe some one might know if it is or not or have the correct one that they can send me?

All it says about the diodes is that they are either D5, D7, D9 etc. It doesn't say what they are.

Yes, it doesn't say but if it were me, I would replace the
blown diodes with 1N4148's (assuming discrete diodes will
fit in the SMD pad space).

Yes, that is exactly the same manual as mine.
How would I connect the 1N4148 2-pin to the 3 pads that are under the SM
3-pin diodes, will this even work?

If it is possible I would have to mount them vertical.

I wonder whether these diodes might not be MMBD4148 or some such?
These are 1N4148-type fast switching diodes in an 3-pin SOT323
surface-mount package.

Mouser and Digi-Key carry several variants of these. The MCC versions
are $.10-$.15 each in onesies and are good to 75V, 150 mA. The Diodes
INc. versions are around half a buck each in onesies, and are good to
75V, 200 mW. I'm not sure whether you'd want apples, or oranges :-)

I'm pretty sure it would work if you get the pads right.
One is probably grounded. One is probably the cathode.
One is probably the anode. You should be able to figure
out which is which using a digital ohm-meter.

I found this just a few minutes ago, on a web site.
The diodes are in a small 3-leaded SM package. Looking down at the
package with it oriented so that the single lead is on top, the
cathode is the top tab and the anode is the left tab on the bottom.

It looks like the bottom right out of the two is not used.
Wonder if anyone can confirm the above?

>In my SG-230, it says 5DL on the top of diode. Don't know if that is an ID:
>code of sorts.

Yes, that's an ID code.

According to one set of notes I've found, Fairchild use 5D as the code
for an MMBD914, which is a fast switching diode similar to the 4148,
in a 3-lead SOT-23 case. The MMBD4148 would have a 5H code. The two
parts look *very* similar on the data sheets, and from what I've seen
in practice they're interchangeable in most applications.

If this is what you've got, then the pinout is as follows: if you
look down from the top of the diode, with the two-leaded side on the
left and the one-leaded side on the right: pin 1 at the top left is
the diode's anode, pin 3 at the right center is the diode's cathode,
and pin 2 at the lower left is not connected to the diode.

The pinouts are the same for the MMBD914 and MMBD4148.

That's consistent with what I see in the data sheets for the
surface-mount (SOT-23) switching diodes of type 914 and 4148.

> a low input VSWR. Have no idea how they achieve it without a matching
> network.

Running more models, and accounting for the coaxial shield, indicates a
dramatic
improvement in radiation efficiency. Resonances are noted to have a much
better match under these conditions, and are highly dependant on coaxial
cable length and position. The NEC code below shows one version
with an indicated efficiency of 76% and a gain in the region of -1 dbi.

With a modified version of the code, including 29 ft of
vertical transmission line, the input impedance was observed to be
near 25 ohms, and resonant at 7.6 MHz. Probably playing around
with various combinations of antenna taps, transmission line length,
and position would achieve something better. Typically the program
takes 2 minutes to run, so optimizing is very tedious.

It appears that many of these ultra compact antenna designs
rely on radiation from the transmission line.

4588. Re: SG-230 problem

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-26 15:47:35 UTC
From: Andy <dx90@blueyounder.co.uk>
Message-ID: <m8IQj.60225$_h7.3456@newsfe05.ams2>
Source record: 25760

I have checked diodes D4, D5, D6, D8, D9 and D10 and all of them check out OK.

All 5 LED's are lit and stay lit when I key and de-key the transceiver. There is no clicking of the relays.

In the SGC Smartuner troubleshooting that can be found here http://www.sgcworld.com/Publications/Downloads/troubleshoot.pdf it says,

For newer SG-230's and other SGC antenna couplers:

1. If LEDs do not light, RF sense diodes and bypass capacitors are suspect. Also

check Q1 (ZN2222) and CPU chip (68HC711).

2. If LEDs do light and coupler does not initiate tuning, check the CPU chip. On rare

occasions, the mixer A1 may fail. Verify if you have clock signal on the output of U3

(74HC393) chip. Verify DC voltage at U11, Pin 1 during transmit. Check R1 and if

no voltage is present, check all 4 sensing signal inputs to the CPU chip - FWD, REV,

PHASE, IMPEDANCE. If you have an input signal, you should see the appropriate

LED light. Also verify RF PWR signal is present.

How do I check the mixer A1 to find out if it's working?

What equipment would I need to check for a clock signal on the output of the 74HC393 chip?

What or where is U11 and how can I determine what one is pin 1?

R1 has voltage.

Horizontal Vee Beams

I have been searching for information on the horizontal vee beam antennas.

I am looking for information on the real ones that are more than 1/2 wave, not a hamstick dipole bent forward and claiming to have 3-6 db gain over a dipole.

Thank you

Thus, the reason folks who attempt to use a balun, feedline choke or balanced line appear to have performance problems with the Tak-tenna -- according to eham.com reviews of the antenna.

Many years ago (~30) I built a simple antenna analyzer consisting of a passive network of resistors, capacitors and diodes. This was placed in-line between the TX and the antenna.

The network had 5 DC voltage monitoring points, selected by a 5-way switch.

Having measured the 5 voltages, you then had to plot on graph paper a set of circles and lines that were proportional to the voltages -- as I recall, 3 circles and 2 lines. The point of intersection of the 3 circles was a measure of the R +/- jX components of the antenna impedance.

I would like to re-create the analyzer, but I can't find the schematic anywhere. I think I first saw it in a UK ham radio magazine, probably some time in the 1970s.

Does anyone here remember it and/or can tell me where I can find it?

It may have been published in more than one periodical, but what you're describing was done by Peter Dodd, G3LDO and Tom lloyd, G3TML and was presented in our QEX magazine for November 1987 back when QEX was still a functional experimenters exchange instead of just an added source of revenue for the League, publishing garbage when that's all they happen to have on hand.

Contact me off group for help.

I failed to mention that the original work was done by Doyle Strandlund, W8CGD and published in QST for June 1965. That may be where you originally read of it since it's closer to the date you recall. Peter and Tom simply took the original work and added software Basic programs to solve the equations mathematically on a Personal Computer. (Two pieces of software are provided. TomSmall and TomBig. TomSmall will run on a programable pocket calculator.).

Hello all,
I have a real doosey.

I built an Octopus, along the lines of the one which was featured in the Dec 2007 issue of QST. This article was written by Geoff Haines N1GY.

The Octopus is a 4 band rotatable dipole, using either Hamsticks or Workman mobile whips

I fitted the following Workman whips: 75m, 40m, 20m & 15m.

I can tune all but the 20m whips, there is naturally an interaction between each of the whips, but 20m simply cannot be tuned. its resonance is around 13.6mhz, and no matter what I do with the whip length it cannot be bought into resonance.

I stress that 75m, 40, and 15m are great.

I have tried the 20m whips on their own as a single antenna and they tune well, but as soon as I offer the second whip to complete the dipole, the resonance drops to 13.6mhz.

When I refit all the other elements, it makes not much difference to the 20m whips as far as their resonance is concerned, it does shift a bit which is understandable.

I have tried rearranging the whips out of sequence around the hub, but that made no difference.

Am I missing something, or are the Workman whips poorly designed?

Is there a preferred way of arranging the whips so that I do minimise interaction between the elements?

Why are the 20m whips the only ones giving me trouble?

I am using an MFJ269 Pro to tune each band.

Thanks,
John

HRBE wrote:
> Why are the 20m whips the only ones giving me trouble?

Probably what is happening is that you are getting a
self-resonance on 14.2 MHz from the 75m or 40m hamsticks.
That doesn't happen with 1/2WL fan dipoles but it certainly
can happen with hamsticks. For instance, if the self-resonant
feedpoint impedance of the 75m hamstick dipole is lower on
20m than the 20m hamstick dipole, you will not be able to
adjust the 20m hamstick dipole for a 1:1 SWR.

Using only the 75m hamstick dipole, find the 20m impedance.
Then do the same for only the the 40m dipole. You can
probably diagnose the problem but I don't know of a
solution.

Ian , I found the circuit you are after in Peter Dodd's book :
The Antenna Experimenter's Guide ISBN 0 9516024 0 3

The book was published in 1991 by DD Publications
address: 37 The Ridings - East Preston -West Sussex BN16 2TW

British Library Cataloguing in publication Data 621.3824

The description of the analyser can be found on pages 3.9 to 3.22

This looks like a really neat device, one of those simple little gadgets
from which you get a huge amount of use.
Hopefully before I got back to work Wednesday I will have one built. Its my
plan to leave out the switch and just bring everything out to test points.

Jimmie

You might want to attach about 100ft as a counterpoise, then it should load
up.

I agree with Cecil,
One of the lower freq whip pairs is resonating on 20M and masking the 20M whips' resonance.
Try this: remove the 20M whips and look for resonance around 20M When you locate the pair of whips that is tuning up, run your finger up and down one of their inductance coils.
You will likely find a great upset in VSWR along the coil- if more than one is found, select the one closest to the base point. Mark this point and then use something like copper tape and a 12" wire to capacity couple to that point. This will have close to zero effect on the band the whip is intended for, but, because it is a voltage loop on 20M, will have a major effect. The idea is to move this whip pair's resonanace well below 14MHz.

Thanks all who contributed.

I re-read N1GY's original and he mentioned in his article about the actual placing of the whips.

I followed his directions and placed the 75m and 40m whips at right angles to each other and the ather two pairs of whips in a like manner.

This then made the whole job a little easier, but the 20m whips are not as sharp in tuning as the other pairs.

I took Dales advice and actually slid a 1" piece of aluminium tubing over the whip and slid them over the whip and found that the VSWR was reduced at a point midway over the loading coil in the whip.

So I have got it working, thanks to you antenna specialists. I appreciate the time taken to reply to my problem.

Regards
John

It is indeed a really neat device. I found it very useful back in the
70s, but at that time I didn't have a computer, so had to draw the lines
and circles by hand. After doing this a few times I rapidly lost the
will to live!

The one thing to watch is the input signal level. I used to use the
low-level driver output from the TX, which was fine. But I don't have
that TX any more, so will have to use the low-power output of the
current TX. Some kind of voltage dropper will be needed to keep the
output level low enough, otherwise the analyzer components will fry.

Andy,
The best distance between stacked beams is the most you can get and stay sort of practical. If the mast between beams is too long then it's going to bend, which is bad. If too short, then those beams might as well be all on the same boom. And until the distance between them gets really ridiculous, they are going to affect each other no matter what you do. So, I guess it depends on what you can manage. There are probably as many 'rules of thumb's as there are thumbs putting up stacked antennas, so, pick one you can live with.

To get a source of signals for test purposes I have been know to apply an
audio signal to the mic input of my SSB transceiver, say 1000Hz then adjust
the mic gain/osc level for the appropriate output level.

With 2 to 4 stations on the same frequency allotment as the old analog
in some instances. At any rate some squeeze 4 in the space that used
to be used by one. They do this at the expense of bandwidth (IE
resolution)

>

They're not! I had one. Also the amp "up there" makes them more
susceptible to overload in interference. They aren't worth the effort
to put them up let alone the price, at least the ones I tried weren't.

>pattern is concerned, which is likely why an onboard amplifier is
>included.

Just a plain old pair of crossed, folded dipoles work just fine. I
have such a set up just below my AV-640 and run about 600 watts on
6-meters.

>

>will be needed.
>

On the big tower I have some long (longest I could get) UHF antennas
with remote mounted amps at 90 feet. One points WNW while the other
points South. They do well for close in stations any where near the
direction they are pointed. I have used them with a combiner but that
results in ghosts on analog and drop outs on digital.

BTW these antennas are about 30 feet below a pair of 12L, vertically
polarized yagis and about 12 feet above the tops of a pair of Diamond
repeater antennas. The tribander is about 8 to 10 feet above the TV
antennas and the 7L 6-meter yagi is about 15 feet above the tribander.
I run the legal limit to the tribander and a 1000 to 1200 PEP on
6-meters. So far no problems.

>In more crowded areas of the country (and in some locations where the
>broadcasters don't want to re-fit their main transmitters) DTV will
>include stations operating in the VHF high band (channels 7-13) and

I receive them just fine on the UHF antennas again out to about 40 to
50 miles.

>
>In a very few areas, there will still be stations operating DTV in the
>VHF low band (channels 2-6), and residents of those areas will still

Only the one in real close (under 30 miles) come in OK on the UHF
antennas. (Ch 5 is about 20 miles)

>

>operating on 2 and 6 meters.

Only problem I ever had was one neighbor having a foot ball party out
in his garage using rabbit ears for an antenna about 120 feet from the
base of my tower. "Hello Test" with 50 watts to the 12L pair at 130
feet would give him a blank screen on Ch 12. I gave him a directional
TV antenna and from then on I was invited over to the parties and free
beer.

Doc, thank you for your reply.

I guess its a case of trying different spacing and see what works best. The closer I can get them together the happier the neighbours will be. Hopefully.

73 Andy

Hi, all, my current project requires a high phase stability (<1 mill degree @ 10 MHz / oC) resonant surface coil. I am trying to use a LC resonant circuit to drive this surface coil, but its phase stability is really poor (about 40-80 mill degree @ 10 MHz / oC). I guess the main problem comes from the used capacitor whose value is easily changed by temperature. so my question is that can the crystal oscillator help me more? or is there any other method to achieve this requirement?

Thanks a lot.

If it is as you suspect, that the capacitor is causing the trouble, why not use a capacitor with low temperature coefficient? C0G dielectric ceramic capacitors are rated at +/-30ppm/C maximum, and I have found some to be very much better than that.

I have no idea what the circuit is that you are driving, but I would expect that if you are driving a high-Q resonant tank, the phase shift will be very rapid with frequency, and that implies the need to use a tank circuit with very good temperature stability. If I'm not mistaken, the rate of phase change at resonance of the impedance of a series RLC, expressed as radians per fractional frequency change, is 2*Q. So for a milliradian change, you need to keep the resonant frequency within f(center)/(2000*Q). A milliradian is 57 millidegrees, so to keep such a tank within 1 millidegree if the Q is only 10, you need to hold the resonant frequency (relative to the excitation) to a little better than one part per million. I'd say that's not a very reasonable goal if the inductor dimensions change with temperature. It will take a decent oscillator just to maintain the excitation frequency to that sort of accuracy. You might actually find a capacitor that will give you that sort of stability, by selecting from C0G caps (or possibly by making your own by plating electrodes on fused quartz...). But that doesn't solve the problem of the inductor itself.

Could you characterize the tank circuit frequency shift versus temperature and compensate by causing the excitation frequency to change synchronously with that?

Cheers,
Tom

They're actually multiplexing two or more digital data streams into a
single RF transmission, coming from a single transmitter and tower.
No matter whether they're sending one HDTV program, or four
independent SDTV digital signals, it's all just one digital bitstream
being sent to the modulator, and sent out in a single 6 MHz slice of
the spectrum (the same slice of spectrum that a single NTSC
transmission would have used).

You're correct, the extra programs are sent at the expense of the main
program... it must reduce its bit-rate, which means either switching
down to a lower resolution, or having more motion artifacts, or
sticking to programs which have relatively little motion on-screen and
are thus easier to compress via MPEG.

>>If you wanted to tune up only one (or a few closely-spaced) HDTV

4624. PL259 Thread standard

Newsgroup: rec.radio.amateur.antenna
Date: 2008-04-30 23:53:38 UTC
From: HRBE <hrbe@bigpond.net.au>
Message-ID: <6E7Sj.6487$ko5.2207@news-server.bigpond.net.au>
Source record: 25796

Hello to all,
I have just bought a Ground plane adaptor off Ebay (yeah I know!) (China! Yeah I know!) it was advertised as a PL259/SO239 male/female thread to enable a groundplane to be fitted to a mobile antenna.

I assumed wrongly that there was an International standard with regard to the PL259/SO239.

Naturally when a known part number is advertised, one would expect that the normal 5/8" x 24 threads per inch standard (UNEF) would be followed.

Not so! What was sent was a 16 x 1mm adaptor.

Naturally the language difference is making it hard for me to convince the seller that he MUST advertise the adaptor on Ebay having a metric thread.

Can anyone tell me if there is a move towards the metrification of the PL259/SO239 connectors?

If this happens all hell will break loose, imagine trying to connect antenna to coax at say a field day or even worse in an emergency situation?

Cecil,

Since you are so concerned about ethics these days I suppose this was an ethical ad hominem.

I have been away for about a month, but it is no surprise to see that this thread lingers on. Fortunately, it appears that all of the technical issues have been decided in favor of well established science. Unfortunately, bickering over the exact meaning of ordinary words remains.

I am thinking MFJ put out some antenna tuners a few years back that had some oddball so239 connectors. The threads almost matched up and youcould force them to mate, but it was not smooth. Also think they would send you some replacements for the so239s.

Thanks again.

I am trying to use temperature compensated crystal quartz to take next measurement. It is a great idea to compensate the frequency shift caused by temperature. Hope it can work.

Green Xenon wrote:
"So I ask what would be the disadvantage of using AM instead of FM for this?"

Short answer is: losing insensitivity to carrier level when recovering the modulation.

Advantage of AM is reduced bandwidth and simpler demodulation.

Advantage of FM is that once a certain minimum carrier level is applied to the detector.
the demodulated signal is independent of the carrier level. A balanced detector allows non-linear RF amplification, insensitivity to amplitude variations, and no response to noise which is amplitude (AM) in nature.

Disadvantage of FM is that it requires about twice the bandwidth of FM.

Best regards, Richard Harrison, KB5WZI

39 mA is probably *not* enough to effectively charge 2000 mAh NiMH
cells. It only a C/50 rate.

NiMH cells have a low "charge acceptance" efficiency at such low
current rates... relatively little of the energy going into them
actually goes into the electrochemistry. The manufacturer's
literature I've read, recommends against using this sort of "trickle
charge" with NiMH cells... it just doesn't work very well. It might
be adequate to maintain fully-charged NiMH cells against
self-discharge, but it's apparently less than idea even for that.

40 mA of charge current might make sense if you loaded the analyzer up
with typical 1000 mAh NiCd cells - it'd be a C/25 rate, and since
this battery chemistry responds reasonably well to low charge rates
you'd probably find the batteries topped up in 36 hours or so.

As it is, you might need to wait a week or more for the NiMH batteries
to charge up, *if* they do so at all.

Seems to me you have three workable alternatives:

- Return this charger and insist that they provide you one with a
more sophisticated/effective NiMH charging circuit. Seems unlikely
to me that they have one at this time - it would require
significantly fancier circuitry.

- Figure out how the charging circuit works, and modify it yourself
to provide a significantly higher charging current. NiMH cells
seem to react well to a C/10 charge rate - around 14-16 hours from
a fully-discharged state seems to bring them up to full power and
break them in properly. This change might require no more than
replacing a single resistor in the charging circuit, depending on
how MFJ designed it.

- Use NiCd cells rather than NiMH (which is what I do with my MFJ 259/269 analyzers). 36 hours of charging should bring 'em up to the Plimsoll line.

- Use a real NiMH AA charger to break in and charge your NiMH cells outside the analyzer, then install them and plug it into the brick for a few hours a day to keep the batteries from self-discharging. Remove the batteries and recharge externally whenever they've been run down significantly.

4638. 75 meter hamstick vs low dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2008-05-01 19:49:00 UTC
From: Buck <usenet01@lumpuckeroo.com>
Message-ID: <2i7k14pdts0lgltr6lv309mp7sqfo0q2tt@4ax.com>
Source record: 25610

If I have a low dipole about 10 feet off the ground for 75 meters,
would it be better if I put a hamstick 75 meter vertical up and
connect the dipole wires to the ground side for a vertical?

John,

I see you have asked this question in several places. I have read some
for what they are worth.

The Japanese manufacturers seems to have gotten a mind about a JIS for an
'equivalent' connector. I don't know this for sure, but I have come
across some incompatible look alike connectors on some well known
Japanese brand high power amplifiers.

Your Chinese parts may have been copied from one of these incompatible
connectors.

Owen

Yes, the distributed network analysis is well
established science. Too bad the lumped circuit
zealots can't see that and still assert almost
zero delays through a 75m bugcatcher coil.

It seems that all energies balance perfectly
when the distributed network analysis is used
for the entire example rather than just half
of the example.

The low dipole is probably much more efficient than the
hamstick and most of the radiation is straight up which
is not necessarily a bad thing on 75m. Your question reminds
me of one on a clinical psychological test. "Would you rather
take one or two days to die an agonizing death?" :-)

I read through the current Part 97 regs a few months ago, and
concluded that it is. See 97.305 (Authorized Emission Types), and
97.307 (f) (1).

The current standard allows a modulation index of up to 1, at the
highest modulating frequency. This applies to all angle-modulation
modes (PM and FM).

The rules aren't specifically worded as "f.m. or p.m. that does not
occupy a wider channel than an a.m. signal having the same audio
modulating frequencies" these days - the restrictions are in terms of
the modulation index, and the general requirement that one not use
"more bandwidth than necessary for the information rate and emission
type being transmitted, in accordance with good amateur practice."

I don't recall having run across any narrowband FM on the HF bands...
I think there are still a few 10-meter repeaters operating around the
country somewhere, but FM HF simplex seems to be either completely
dead, or used just by occasional experimenters.

That may explain the problem I had with a couple of connectors . I was
able to borrow a die to run over them. The metric threads must be very
close to the SAE. After rethreading them they worked but I didnt like
the way the threads looked so i trashed them.

I think the original post needs a couple of questions asked.

Agreed the low lying dipole is ideal for a NVIS antenna.
It would be interesting to see what kind of results would be had for
contacts greater than 600 miles between the two antenna's.

That Hamstick isn't going to be very efficient, so I guess it comes down to whether or not the reduced efficiency of the dipole at the desired DX angle allows for greater signal than the bad efficiency of the Hamstick at all angles...

Suffice it to say that it probably isn't a very good option to run a Hamstick setup at home when there are any other options available.

Your not going to gain anything from the swap. I've compared a full size
dipole to a hamstick dipole on 80m at the same hight. The dipole was
20db (about 3 S-units) better than the hamsticks. You will not gain
anything close to 20db by putting the hamstick dipole up higer. On 40m a
hamstick dipole is only about 10db worse than a full size dipole, better
still on the higher bands. And yes I'm talking about hamstick dipoles
using the right models for each band. On 80m the 2:1 SWR bandwidth is
about 60KHz, wider on 40m but still narrower than a dipole on all bands.

Ham stick dipoles seems attractive, but they fall into the better than nothing class on the lower bands.

Interesting question but I was responding to the question in the thread tille.

FM usually occupies about twice the bandwidth of AM. Spread spectrum ordinarily occupies more bandwidth.

Spread spectrum was patented by Nikola Tesla in 1903. FCC now codifies rules for spread spectrum in Wi-Fi, Bluetooth, cordless phones, etc.

Terman says about twice the bandwidth is required for FM as compared with AM on pages 589 and page 590 of his 1955 opus.

The signal for spread spectrum is a form of FM but usually the signal is transmitted on a bandwidth considerably larger than the frequency content of the original information says Wikipedia.

Best regards, Richard Harrison, KB5WZI

FM is almost essential to repeater operation due to the inherent
automatic gain control of the FM mode. Once the weak signal point called
the "FM improvement threshold" is exceeded, further carrier strength
increases have no effect on the recovered modulation. The pip squeak is
as loud as the power house. Remodulate that on the repeater output.

Yes, they normally do up most of the way and then bind just before the inner
part has mated with the serrated teeth, so it is easy to miss if you don't
check that the cable is not free to rotate.

The invention of spread spectrum is generally credited to George
Antheil and Hedy Lamarr (yes, the actress) and their patent of 1942.

Green Xenon wrote:
"But wouldn`t multipath intrference be as much of an issue in FM as in AM?"

Ionospheric multipath mucks up both FM and AM because the sidebands have both phase and amplitude altered almost randomly in transmission. However, FM is less sensitive to amplitude variations and reduces the apparent fading. But, a better way to reduce effects of fading is by diversity reception which automatically switches to the best available signal given several options which are from different carrier frequencies, antenna locations, or antenna polarizations.

Best regards, Richard Harrison, KB5WZI

Yes, I believe Lamarr and her husband encoded several tones in sequence using a player-piano roll. The system was used in WW-2. Poor old Tesla only invented the a.c. power system, wireless power transmission, and demonstrated his remote control of a boat using spread spectrum to avoid interference more than 40 years before Hedy Lamarr`s patent. T.A. Edison did his best to deny Tesla credit for anything. That`s commerce.

Thanks for adding "usually" to your original statement.
I was just pointing out that if the FM peak deviation
is equal to the maximum modulation frequency, then the
FM signal occupies the same bandwidth as AM. The S/N
ratio advantage usually enjoyed by FM over AM occurs
when the FM peak deviation is *greater than* the maximum
modulation frequency. FM seems to have been the original
"spread spectrum" mode. :-)

> Best regards, Richard Harrison, KB5WZI

George Antheil and Hedy Lamarr were never married. Antheil was a
neighbor.

The didn't encode "serveral tones in sequence on a player-piano roll",
they used a piano roll to produce frequency hopping between 88 different
frequencies with the intention of making radio guides torpedoes hard
to detect or jam.

The first practical use (after technology caught up with the concept)
was by the Navy during a blockade of Cuba in 1962 based on the work
started in 1957 by Sylvania Electronic Systems.

While Tesla and several Europeans had their fingers in various frequency
hopping schemes, the general consensus is that Antheil and Lamarr were
the first originators of the basis for spread spectrum radio systems as
used today.

Both Antheil and Lamarr were given a special award in 1997 in recognition
of that fact.

Other than that, you mostly got it right.

To greatly simplify, spread spectrum is random frequency hopping to
discreate carrier frequencies and says nothing about the modulation
of the carrier.

John,
The idea I have is to make a vertical ground plane with the HamStick.

>Ham stick dipoles seems attractive, but they fall into the better than
>nothing class on the lower bands.
>
>John Passaneau

i fully understand that the HamStick is not a great antenna fro that
band, but how would the vertical ground plane made of a HamStick and
two full length radials compare to a dipole at the same 10 foot level?

what would the angle of radiation be like?

But frequency-hopping is only one form of spread spectrum.
How about the direct sequence form, DSSS?

My suggestion would be to download the trial version of EZNEC and model a 7 wire over ground. That is an easy model to do and will tell you what the pattern will look like. As to the gain it will be just about the same as my tests, about 20db down from a full size antenna. The reason is hamsticks are very lossy on 80m and the bandwidth will still be about 60KHz. Anyway learning how to model antennas is a lot of fun and you can try out a lot of different antennas easly. I can say from experance that modeling works. Everything that Ive carefuly modeled worked just like the model.

That is one specific form of spread-spectrum transmission (FHSS or frequency-hopping). This form tends to be used a lot in lower-cost consumer electronic gear (older-generation cordless phones, for example).

There are other forms of spread spectrum in common use, and in these forms the spreading is tied to the modulation scheme to at least some extent. Two examples:

- Direct-sequence spread spectrum (DSSS). A digital bitstream is XORed with a high-speed pseudorandom "spreading sequence", and the carrier is modulated by the resulting high-speed bitstream. The basic carrier frequency going into the modulator doesnt't change (it's fixed on a per-channel basis) but the energy is spread out as a very broad set of sidebands. 802.11b WLAN uses DSSS.

- Orthogonal frequency-division multiplexing (OFDM), which uses a large number of individual carriers, typically spaced at regular intervals, each modulated at a relatively low rate with some portion of the information being sent. Here, too, the frequency of each individual carrier tends to be fixed. 802.11g, DMT (discrete multitone) DSL modems, and the venerable Telebit Trailblazer phone-line modem use OFDM.

Very-wide-band FM (i.e. FM with a high modulation index) carries little of its energy at the carrier frequency - most of it is in the regularly-spaced sidebands, located at offsets from the carrier which are multiples of the modulating frequency/frequencies. In this sense, its spectrum use would be not dissimilar to that of an FDM spread spectrum (although it would generally not be OFDM because the sidebands aren't spaced in an orthogonal manner).

Cecil, W5DXP wrote:
"But frequency hopping is only one form of spread spectrum."

Yes. No more than two frequencies are required to switch between, though the transition produces more frequencies than the originals. Carson`s rule is a close approximation of the required bandwidth and is used by the FCC to determine bandwidth:
BW= 2(Peak Deviation + Highest Mod. Freq.)

FSK or frequency shift keying uses only two frequencies to represent ones and zeros. Switching produces FM and is a form of spread spectrum transmission defined as:
A communications technique in which many different waveforms are transmitted in a wide band. Power is spread thinly over the band so narrow-band radios can operate within the wide band without interference. FSK is often done within the audio frequency band with no radio necessarily used in transmission.

Best regards, Richard Harrison, KB5WZI

I believe that you're mistaken on this point, Cecil.

As I understand it, the spectrum of a frequency-modulated carrier will have energy at the carrier frequency (except at certain very specific modulation indices), and energy at offsets from the carrier which are equal to the modulating frequency and all of its harmonics.

It's entirely possible (and in fact common) for an FM signal to have energy at frequencies which are further away from the nominal carrier frequency, than the maximum instantaneous deviation of the carrier would suggest. For example, a carrier which is modulated with a 1000 Hz tone, but only to the level of having a maximum peak deviation of 500 Hz from nominal, will still have sideband energy out 1000 Hz and 2000 Hz away from the nominal carrier frequency.

This is *really* counter-intuitive, and I haven't been able to fully wrap my brain around the question of just how the math works... but the math says that it's true, and my own spectrum measurements show that it's true.

An FCC-approved NBFM phone signal, which has a modulation index of no more than 1.0 at the highest modulating frequency, *will* have energy out further than the peak deviation would suggest. There will be some amount of sideband energy located out at twice the highest modulating frequency, and a bit at three times.

The levels of these further-away-from-nominal-carrier sidebands will be relatively low - they don't start to become appreciable until you get to a higher modulation index.

An AM signal being modulated by the same intelligence signal would not have any energy out at the multiples, *if* it was generated and transmitted in an entirely-distortion-free manner.

My guess is that in practice, NBMF (per FCC regs), and ham-grade AM, probably have very similar bandwidths. All it would take for the AM signal to be spread out as far as the FM signal, would be a bit of

nonlinear distortion in the audio chain, mixer, or amplifier chain...
this will create a second-harmonic sideband.

I did an introductory presentation to a local hamclub last year (with
some math, admittedly simplified and approximated and covered up with
moderate amounts of hand-waving) which explains some of these
concepts. I included some plots of actual measured spectra, generated
by an HP signal generator and captured using an old Systron Donner
spectrum analyzer.

I think it would compare badly to the dipole.

With the dipole, you'll have working in your favor the basic radiation resistance of a dipole in free space, reduced by the proximity of the dipole to the "reflector" (the lossy soil). Working against you, will be the losses in the soil. It'll certainly be a cloudwarmer... good for NVIS, not for DX as there will be little energy at a low radiation angle.

If you short the dipole wires and use it as a two-wire sort-of-elevated radial set, the radiation resistance of these wires will be very close to zero - the far-field radiation from them will cancel out almost entirely. You'll still have substantial losses in the soil, I think, as the wires are only a small fraction of a wavelength above the soil surface. The radiation resistance of the HamStick itself is going to be quite low (an ohm or so??), and it certainly has a substantial amount of loss resistance.

My SWAG is that by making this change, you might drop your radiation efficiency from 25% (low dipole over lossy ground) to 5% or less (lossy short vertical, over an inadequate radial network with substantial ground losses). Don't trust these numbers!

>what would the angle of radiation be like?

Probably much like that of any other very-short monopole over a lossy ground... pretty much omnidirectional, with a modest null pointing straight up.

It *may* have more low-angle radiation in the pattern than the low-dipole arrangement, but I think you'd lose most or all of the pattern advantage due to the lower radiation efficiency.

Yep, you're right. A modulation index of about 0.6
yields approximately the same bandwidth for AM and FM.

Assuming a 7 ft monopole, with a lumped element inductor
(located in the middle of the vertical) of Q = 500,
and 100 W input. The total radiated (sky wave) power is 1.4 W.
The gain is -12.7 dbi with a take-off angle of 23 degrees.
At resonance the input impedance is 14 ohms.

73,

Frank

I have these following items I can't use and I would like to trade for items I can use.

Shure Hand Held Mic.. cm 16r This is a noise canceling mobile mic. with a 6 pin plug NEW.. and I can't use it.

Slinky Dipole antenna. 10-80 mtrs.. With directions. This is a new antenna and it was never installed.

Motorola 12 volt power supply. I was told this is 12 amps.. could be 16 maps

Model HPN 1004A.. Needs minor work.. fraid power cord. other wise its working. not enough current for my needs. And I can't store it in my small apartment.

Motorola white external speaker. No mounting bracket. But in nice shape,

I would be interesting in trading for 20-25 amp power supply,, 12 volts Need not be working. Astron.. or something like it. Or power supply parts.

Antenna tuner,, or parts for a antenna tuner. If it needs work I am open for that. MFJ.. or someother

Please e-mail me at mkulyk@optonline.net

John-

I built the Octopus, but decided to go one further. I added a Ten Meter vertical whip on top, thinking the other elements would act as an effective counterpoise. It didn't work! Apparently a Ten Meter counterpoise element is needed.

Just using the basic 4-band design, it seemed to have quite good SWR dips, and responded to tuning. It did not have your problem. It does use whips like (or close to) the ones in the article, not true Hamsticks.

However, I kept trying to add Ten Meters. By changing one of the ground elements to a hot element, and adding two 45 degree upward-tilted grounded elements on a bracket, I was able to "share" one of the dipoles. If one band's hot element is on the north end, then its grounded element is the southern 45 degree element, and vice-versa for the second band.

I tried various pairings of Ten, Fifteen and Twenty, but there was always one band of the two that suffered with either a poor SWR dip and/or a center frequency shifted downward. I ended up sharing Fifteen and Ten Meters, with Ten Meters being the band that suffered. Even with a poor dip, the SWR is below 2:1 over the entire Ten Meter band.

So far, Ten Meters is the only band I've gotten signal reports on, and only for local contacts. In that situation, it seems to compare favorably to a mobile installation with a single whip.

Thanks Fred for your comments.
Today I tried out the 40m band and got great reports from a mobile op who was over 400miles away to the south of me and another op in his shack about the same distance north, both said I put in a very good signal, and strangely enough I was the same signal strength in comparison to another operator who was operating from his shack 15 miles due west of me, to both other other operators.

I intend to put a 2m/70cm antenna on top, but to do this I will have to do some machining to the hub as it was machined out of a solid billet of aluminium.

It has certainly exceeded my expectations.

You really should try to understand the context of the various quotations from Terman.

In his _Radio Engineering_, Third Edition (1947), he points out that "When the modulation index is less than 0.5, i.e., when the frequency deviation is less than half the modulating frequency, the second and higher order side-band components are relatively small, and the frequency band required to accommodate the essential part part is the same as in amplitude modulation." This is, of course, what is considered to be narrow band FM.

Unlike an AM signal with its one pair of sidebands containing replicas of the modulating signal, any FM signal contains an infinite number of pairs of sidebands. However, as Terman and any other communications text points out, the relative strengths of some of those sidebands can be made to be very small by the choice of modulation index. In the case of NBFM, all but the first pair are small. That first pair are spaced the same distance from the carrier as AM sidebands, so the bandwidth is essentially the same as for AM.

You can, of course, increase the modulation index which increases the bandwidth by increasing the amplitudes of higher order sideband pairs, making wideband FM. The advantage of doing this is that you can improve the signal/noise ratio of the received signal as a trade for the increased bandwidth.

So FM can be as narrow in bandwidth as AM, or any greater bandwidth, all depending on the modulation index. Saying that "twice the bandwidth is required for FM as compared with AM" is simply not a correct statement and, if said by Terman, was taken out of context which surely qualified it.

And the Q of a hamstick is probably a lot closer to 50
than to 500. Someone else reported the hamstick as -20 dBd.

4680. Ground gain on real ground

Newsgroup: rec.radio.amateur.antenna
Date: 2008-05-03 17:00:23 UTC
From: Antonio Vernucci <vernucci@tin.it>
Message-ID: <481c9a18$0$29601$4fafbaef@reader1.news.tin.it>
Source record: 25652

I am simulating on EZNEC an antenna yielding a gain of about 13.5 dB (at zero deg. elevation) when in free space.

The same antenna, placed on an ideal ground, shows a gain of about 18.8 dB (at 10 deg. elevation), thanks to the so-called "ground gain".

If the antenna is placed on a non-ideal ground (according to EZNEC modelling), its gain becomes 18.4 dB.

I am surprised of the small gain difference between the ideal ground case and the non-ideal ground case (just 0.4 dB). As a matter of fact, while the ideal ground may be regarded as a perfectly conductive plane, the non-ideal ground is something having a significant ohmic resistance. I would had thought that most of the RF power incident on a plane having a significant resistance would be absorbed (and hence not reflected).

Any comment please?

You must be modeling a horizontally polarized antenna. The attenuation caused by ground reflection is quite different for horizontally and vertically polarized fields. When the field is horizontally polarized, nearly any reasonable ground gives a near-perfect reflection at low elevation angles. Only at high elevation angles will you see much difference caused by ground quality.

Unfortunately for people using vertical antennas, the story is quite different when the field is vertically polarized.

There's a good discussion of the effect of imperfect ground and derivations of the ground reflection coefficients in any edition of Kraus' _Antennas_.

"You really should try ro understand the context of the various
quotations from Terman."

I do.

I did not give the quotation from Terman, only its gist. Here it is:
"A useful rule is that a frequency modulated wave contains sideband
components of importance on either side of the carrier wave over a
frequency interval approximating the sum of the frequency deviation and
the modulating frequency. The total bandwidth in which most of the wave
is contained is then twice this value."

The original posting in this thread read:
"Most cell phones and wireless routers, modems, and access points that
use spread spectrum usually broadcast and receive their data on FM-radio
waves. Just out of curiosity, I ask why not use AM?"

Nothing about narrow-band FM in the question and I responded:

"---losing insensitivity to carrier level when recovering modulation."

I did not take Terman out of context to distort his meaning. Ternan was
merely restating Carson`s rule which is the same approximation the FCC
uses to determine bandwidth. I quoted this in my May 2, 3:28 pm posting.
I`ve used this to calculate bandwidth many times with no citations from
the FCC yet.

I make plenty of mistakes but I see only one I`ve made in my postings in
this thread and that is an instance where I typed FM when I meant AM and
I immediately corrected it in the next posting.

Best regards, Richard Harrison, KB5WZI

I would think it would be hard to design a coil with a Q of 50.
I tried to find a picture of a Hamstick to estimate the Q,
but no luck. Anyway, assuming the Q is 50, NEC returns
the following results:

Structure efficiency - 5%
Total radiated sky wave (with 100 W in) = 180 mW.
Input impedance - 112 ohms.

Good to know. I would have otherwise thought that even sea water is not a good reflective plane, its resistance not being very low.

The resistivity of sea water is high compared to metal, but very low compared to air. But what counts is its intrinsic impedance compared to that of free space. At 10 MHz, the magnitude of salt water's intrinsic impedance is about 4 ohms, compared to the 377 ohms of free space. So it does a good job of reflecting waves when air is at the other side of the interface.

EZNEC will tell you the intrinsic impedance and other information about any Real ground if you select Ground Info from the Utilities menu in the main window.

Easy, I turn up the peak deviation intil twice the bandwidth is occupied with FM as would be required for AM. It is arbitrary and depends on peak deviation. If you make the deviation less than half the modulating frequency, the bandwidth occupied will be about the same as required for AM.

4690. To Find Your Soil's Electric Conductivity

Newsgroup: rec.radio.amateur.antenna
Date: 2008-05-04 12:19:53 UTC
From: KA3VID <whax44@NOspamgmail.com>
Message-ID: <JRhTj.3154$ch1.2374@trndny09>
Source record: 25662

Fellow radiators:

To Find Your Soil's Electric Conductivity

1) Go to: http://websoilsurvey.nrcs.usda.gov/app

2) Click on the big green button, "Start WSS".

3) Follow step 1 of "Three Basic Steps" on the first page.

Typing your address under "Quick Navigation" is the

easiest method. Remember to spell out street, circle...

When using the + and - zoom feature, click on + or -.

Then place the cursor at the point you wish to be the

center of your next map and click.

4) Click on "view".

5) Click AOI tab which is just above the map and outline

(draw a box

around) your Fresnel Zone.

6) Follow the second step "View/Explore" by clicking

the "Soil Map" tab.

7) Click the "Soil Data Explorer" tab.

8) Click the "Soil Properties and Qualities" box which is

just above the map.

9) Click the "Soil Chemical Properties" box.

10) Click the "Electrical Conductivity" box.

11) Toward the bottom of the page, locate "Top Depth" and

enter 1.

For the bottom depth enter 144 for 14 Mhz, 360 for 1.8 Mhz.

12) Click inches.

13) Click "View Rating".

14) In the table, read in the column "Rating (millimhos

per centimeter)".

15) Use the millimhos/centimeter number as mS/m.

Thus, 17 millimhos becomes 17 mS/m. This is the

electrical conductivity of your Fresnel Zone.

16) This page is printable from your screen to your printer.

Best regards,
Will

John-

Yours sounds like it is relatively weatherproof. Mine is definitely not. It may be possible to use a round cap for a 4 or 5 inch PVC sewer pipe to construct one that is. It might also be possible to mount all 10 elements of a 5-band antenna along the circumference.

A vertical 2m/70cm antenna would be worth a try. If it doesn't work against the grounded HF elements, adding a few short resonant radials should correct it. Worst case, a second feed line might be needed.

It occurred to me that my criteria for a "good dip" may be different from yours. I consider it to be one that is distinct, at least 1.5:1 SWR but not necessarily down to 1:1. Using a rig that has an auto-tuner, useable bandwidth should be at least as good as the spread between 3:1 SWR points.

I made one additional modification to mine, swapping one insulated element with one grounded element on the bracket. By pairing Ten and Fifteen Meter elements as before, the previous problem seems to have gone away.

(I'm having trouble posting, so this may appear twice!)

This might be fun to do, but it probably doesn't really tell you your soil's conductivity, which can vary a great deal from lot to lot and even within a yard. And if it does, it's likely to be only the surface conductivity. The skin depth for average soil is around 12 - 15 feet over the HF range, so substantial current flows to that depth and below. Typical soils are stratified, with potentially very different conductivities at different depths.

So, after going through this exercise, you have a number. But that number is of no real use.

The original PL-259 was a World War 2 US military JANAP standard.
It had specifications for all the critical fit parts of a PL-259 connector.
Eventually the JANAP standard morphed into a US Mil-Spec Standard.
The current standard hasn't changed much since WW2.
A metric thread does not meet the standard.
If somebody says its a PL-259; they should meet that standard or say it is
similar but NOT compatible.
Too many manufacturers have gotten sloppy in their QC.

In another forum, I was informed that the signal for the vertical was
very low at every angle compared to the dipole.

One of the things i was thinking about was if it would be beneficial
to add a good ground radial to the mobile whip on the car, once
parked. however, it is obvious that if one can raise, even 10 feet, a
full sized 1/2 wave dipole, it would produce much better results being
left in the dipole configuration.

Thank you to all who participated. (Even to the one who simply said
"NO"). that was a short, sweet and to the point answer. :)

It just occurred to me that I have over looked something that might have some use in this discussion. I just realized that this thread is about a low dipole compared to a vertical Hamstick antenna. I reported that I have compared a Hamstick dipole to a full size dipole and that it was down 20db from the full size dipole. I can also report on a Hamstick vertical compared to a full size dipole on 80m. For some years I've been using a phased vertical system as a receive antenna on the 80m SSB Dx window. It is 2 Hamstick's spaced 1/16 wave apart and feed 90 degrees out of phase with a relay system that lets me switch directions. As a receive antenna it works very well. A friend that has a 900'plus beverage tells me that it compares very well. For me it gives me about at 15db signal to noise advantage over my transmit dipole. The front to back is also about 20db in the most favorite direction. But here is the part that is germane to this thread.
The signal level compared to the dipole is still about 20db down. I don't care as receivers have a lot of extra gain and the increase in signal to noise makes all the difference. I don't have much of a ground system, just 4 10' radials under each vertical but putting down a good ground will not make up 20db, no way. The main advantage that a beverage has over this antenna is that it will cover several ham bands and the Hamstick verticals are only good for about 100Khz around the DX window but that is all I want and it fits in my yard as the spacing is only about 30'.
So I can say that a phased hamstick vertical on 80m with a poor ground is also about 20db down from a full size dipole at 40'.

It all makes good sense. The best 75m mobile antennas
are about 10 dB down from a 1/2WL dipole. The hamstick
is about 10 dB down from the best 75m mobile antennas.

This is probably going to seem like a stupid question to most of you, but I'm looking at an antenna pattern, which I've seen before. It's a representation of db over degrees. It's the typical pattern showing the lobes of the radiation that the antenna emits. My question is, on what scale are the db represented over what distance? Is there some universal preset saying that -10db is 100m or something like that?

It's the lack of a decent radial system which makes me
look at it in a negative manner..
It's quite possible for the short vertical to outplay the
low dipole for DX, but... I don't see it happening with
only 2 radials and low to the ground.
The hamstick would actually work better mounted on a
vehicle than it would in that 2 radial scenario I bet.
So it's more the ground radial problem, rather than
the short radiator itself.
On 40m, my mobile outplays my 35-40 ft high dipole
to DX. But, I don't know if that would be the case with
two low radials, vs the usually better RF ground that
my vehicles provide.
With a low vertical on 80m, two radials ain't gonna
get it done as far as avoiding ground loss.
And the short vertical makes things even more critical.

For NVIS use, the low dipole would *smoke* the short
vertical with two radials. I've run low 80m dipoles 5-10 ft
off the ground when camping, and still had fairly
decent results to regional stations.

Hi Andy

You can get some good comparison of analyzers from PA1ARE
http://homepages.ipact.nl/~pa1are/index.html
You will find good information in his Analyzer section.

========
Using a MFJ259B (range: 1.8 to 174 MHz) myself I use it regularly for
the following :

1) Finding settings of an antenna matching unit (I prefer NOT to use
the word 'tuner') for the various HF bands.

2) Adjusting VHF antennas (gamma match) for minimum reflected power
(SWR)

3) Determining SWR curve of an antenna within a specific freq range
(part of the technical assessment for the UK Foundation Licence)

4) Determining coax loss

5) Determining inductance of resistors at various frequencies

6) Measuring value of inductors and capacitors at different frequencies

7) Measuring resonant freq of tuned circuits (including self resonance
of inductors /RF chokes)

I find the instrumment invaluable ,even if its accuracy would be debatable.

the scale from the center of the plot to the line is arbitrary just to keep
the plot on the paper. it has nothing to do with a physical distance of how
the measurement is made.

An antenna pattern is a graph of relative signal strength versus angle. It's not a graph relating anything to distance, nor is it a graph of absolute field strength. What it tells you is how strong the signal is in each direction compared to some reference (0 dB). If you stay the same distance away from the antenna and walk around it in a circle, you'll see the field strengths vary as shown on the graph in the various azimuth directions. This will be true regardless of the distance you choose. (I'm making the assumption here that the graph is for the far field and you stay in the far field for your observations.) dB is a relative measure, so all you can immediately tell from the graph is how strong the signal is in one direction compared to what it is in another, at the same distance.

There is an absolute reference, however, the dBi. That's the field strength an antenna will produce compared to the strength of an isotropic antenna -- one with a perfectly spherical pattern -- with the same power applied. So if you know the gain in any direction in dBi, you can find the field strength for a given power input in V/m or A/m or the power density in W/m^2 at any distance in that direction, and in other directions by using the graph. When in the far field, the field strength decreases in inverse proportion to the distance, so if you know the field strength at one distance, you can find the field strength at other distances in the same direction. The field strength is also directly proportional to the square root of the applied power, so if you know the field strength for one power level, you can calculate what it will be for others.

In short, what you need in order to find the field strength at any distance and direction are:

1. The graph showing the gain in that direction compared to some reference.
2. The dBi or field strength value which that reference represents.
3. The power being applied to the antenna.

IMO, Ni-Cads are a royal pain in the neck. Instead,
I use a YUASA gell cell NP1.2-12 at ~$20. I Velcro
it to the MFJ-259B as it has almost the same form
factor. It is easily recharged using an Astron 12v
(13.8v) power supply, i.e. no "battery charger"
required. After using the NP1.2-12 to power the
MFJ-259B, I would NEVER go back to standard batteries.

If one removes the battery holder, the NP1.2-12 will
almost fit inside the MFJ-259B. When I get time, I am
going to modify the MFJ to accomplish that feat. MFJ
missed a selling point by not making the 259B case a
couple of mm larger to accommodate a standard gell cell.

Good explanation, Roy. (I didn't want to quote the whole article)

Just an additional comment. In the case of a plot of *electric field*
intensity (in volts/meter) vs azimuth angle, usually applied to standard-
broadcast AM stations, the radial distance on that plot does map directly
into the distance at which a particular field strength can be received.
Looking at such a plot, such as those found in the FCC database, does
give a (rough) idea of the "range" of a particular station in various
directions and helps explain why some stations, relatively close-by,
do not reach a particular location (their antenna pattern has a null
in it in that direction).

An interesting program, called BCmap, illustrates this by overlaying
a map of North America with the patterns of AM stations on a particular
frequency, or set of frequencies. It may be downloaded free of charge
from:

http://www.tonnesoftware.com/bcmap.html

Sorry, my mistake, that is not the battery I use
although it will work. The YUASA battery with the
perfect form factor for the MFJ-259B is the NP2-12
at ~$48. That one failed after many years of use
and I am going to replace it with an NP2.3-12 at
~$29 which is 1.7 times as thick but is higher
capacity and costs 60% as much as the NP2-12.

Andy,
I own an MFJ269 Pro, and us an external SLA battery without any internal batteries fitted , and no problems at all.

I have the SLA in a small shoulder bag and connected to the external DC socket, makes the unit very protable and lasts for hours.

No, no problems whatsoever. After trying internal
batteries, everyone I know has gone to an external
gell cell.

I have my gel cell rigged up in a pack I can put on my belt. I also
have an additional 5 and 3 volt regulator circuit so I can use the
pack with my digital cameras. Even used it to inflate an air mattress.
My wife wants me rig up a connection for her cellphone. I am
intentionally dragging my feet on that one.

I'm trying to come up with some ideas for multi-op field day station isolation. Main problem will be front end desens between Voice and CW portion of the same band. Main concern is on 20M

I'm thinking simple stub filters. Though they are wide, I would think that there would be a few DB of isolation 100Khz away. Perhaps several in parallel to narrow it up a bit.

Would a simple LC resonant circuit with perhaps 20-30Khz of BW work?

Any thing else I should be considering?

Thanks You!

In general, you can make a better filter in a given volume by using lumped LC filters at HF frequencies, than by using transmission line stubs. The reverse is true when you get into the hundreds of MHz region.

You need high Q elements to get good isolation and not incur too much loss when frequencies are spaced that closely. A saving grace is that you probably don't need a whole lot of attenuation, assuming the receiver front end you're trying to protect isn't too bad. It's not like you're trying to completely kill the offending signal, just get it down to where it doesn't cause trouble. Intermod (third order distortion) generally drops around 3dB for every dB you drop the signals causing it. Desense should similarly go away fairly rapidly as you drop the big signal levels.

Looks to me like a design with five coils and five capacitors and what at least I consider practical values should give you 25dB differential between the passband and the stopband, with a 100kHz separation between the two, and a loss of about 5dB in the passband if you use Q=500 coils. Air core coils about an inch and a half in diameter should give you Q that high. I haven't tried optimizing the design, and may be able to do a bit better than that with the same number of parts. I can imagine building it "on the cheap" in a string of tin cans soldered together, or else by using pieces of copper-clad soldered together. (I've built several somewhat similar filters using copper clad for the shielding, and they work quite well.) Would a suggested design be helpful?

Another option (or something to consider in addition) is a small loop receiving antenna that you can orient to null the other transmitter.

I believe N6RK just gave a paper on doing this, though with emphasis on lower bands. He may have a PDF of the paper he'd be willing to share.

Cheers,
Tom

Here's what I did to solve the rechargable battery issue with the
MFJ-269B antenna analyzer.

The charge rate is way too slow using the internal charge circuit, so
to speed up the charging process using intenral AA NiMH internal
batteries, in the factory battery holder, I installed a power barrel
jack on the bottom of the meter. To charge, I plug in an external
charger into this new jack, and when plugged in this disconnects the
batteries and charger from the unit. You can NOT simply plug a charger
into the factory ext. power jack, so now my analyzer has two jacks, of
DIFFERENT sizes so I do not accidently plug the wrong thing into the
wrong jack. I inserted a 0.5amp fuse inside the charger, in series
with the + battery wire so that if your external charger is set for
too fast a charge rate the fuse will blow (e.g. I have a charger which
can be set for various charge rates, for AAA to D size batteries,
NiMH, etc., up to 50w total).

---

To both posters above, note that the relative field, h-plane azimuth patterns for AM broadcast stations such as published on the FCC website and in the BCmap program are acceptably accurate only very close to the radiator(s) -- about 1 km or so. These are the net radiation patterns of such stations just beyond the near-field radius, where for such short paths, frequency and earth conductivity have relatively little affect on groundwave field intensity.

Earth conductivity, earth curvature and frequency become very important for long groundwave paths, and those perfect relative field patterns no longer are a very good indicator of relative field intensities for such groundwaves.

There are other websites that do take the applied r-f power and frequency, earth conductivity and earth curvature into account when calculating the distance to a given groundwave field intensity resulting from the h-plane ERP in each direction that is "launched" by an AM broadcast station.

The link next below leads to a graphic showing three groundwave field-intensity contours for WJR, Detroit, which is a 50 kW, non-directional, fulltime station on 760 kHz, using a single, 195-degree monopole radiator.

These groundwave field intensity pattern shapes would be perfect circles for values plotted ~ 1 km from the antenna site.

But the more distant contours shown on this site are far from circular, as a function of the varying groundwave propagation conditions in various compass directions from the transmit antenna location.

coax stubs are too broad... use lumped filters if you need them, but its
hard to get real good isolation within a band. one proven way to help
prevent problems is proper prior planning of the layout, put the cw and ssb
stations as far apart as possible. if both are using dipoles or yagis
arrange them so they are in each others nulls when pointing in the prefered
direction. using one with horizontal antenna and the other vertical may
also help.

Dear No Spam,

A simple resonant circuit centered on 14.05MHz with a 3dB bandwidth of 20KHz is a circuit of Q = 705 which is tough to make and even then will not provide enough attenuation at 14.15MHz to be of much value.

I have done exactly what you want to do and you will not accomplish it with LC filters and stubs alone. Assuming you wish to run 2 stations on 40m or 20m simultaneously and demand a minimum separation of 80KHz which is only about a 0.5% spread (on 20m) you will need to be more creative. Transmitter phase noise and receiver blocking dynamic range are the 2 issues and both are about the same magnitude problems. Your friends in the solution of this problem are the allowed 1000' diameter circle for FD, the different antenna polarizations, and the antenna patterns. Expect to need about 60dB isolation between 2 antennas on the same band if you are using current mid range transceivers such as the IC756PRO3 and maybe about 45 to 50dB isolation between the antennas if using transceivers such as the K3. With less isolation you will still make contacts but the noise floor will rise and you may hear receiver artifacts. If you wish to discuss this further please contact me directly.

73,
Larry, W0QE

I'd love to be able to find designs for single-band filters for FD use -- this year we'll have 2 or 3 IC-7000 stations, at least one yagi, a vertical, and an nvis.

Something like a low-pass for 80, high pass for 10, and bandpass for 40, 20, and 15, that can take 100W, including 100W for at least a few seconds on the wrong band... That kind of thing happens after you've been up for too many hours!

Of course Larry's right: any transmitter phase noise will be a
problem. Especially with the density of signals typical on FD, 3dB
loss in a receive filter won't be much of a problem most of the time,
but in a transmit filter it's another issue. 3dB passband attenuation

was about what I got in the filter design I was playing with this morning, assuming coils with a Q around 400, which should be fairly easy on 14MHz. That gave better than 25dB attenuation 100kHz away, which should be a huge help. If you can get the coil Q up enough, then the filter can be used on both transmit and receive, and you'll get the same improvement in phase noise output performance that you get on receive in rejecting the adjacent band. 100 watts will be incentive to use large enough coils that the Q will indeed be pretty high--assuming you don't do anything too stupid in the construction. There are significant advantages at a multi-transmitter FD site in having a receiver that tolerates strong signals well, and also in having a transmitter that has low phase noise.

Cheers,
Tom

These are some great things to think about.

Perhaps I may have been hasting into concluding we needed the filters in the first place when some more easily implemented practices should be tried first.

I think the best thing will be to only use the "good" radios on the same bands and better utilize spacing and polarization to see what best we can achieve. One of the other ideas I think we will be considering will be to limit power for CW and digital modes as well. I am also having high hopes of separation as I think there may have been some coupling induced by the common ground and shared power supplies. Perhaps having two compounds with separate infrastructures and space would reduce problems to a more tolerable level.

Thank you all for you response!

Don't neglect common mode feedline current as a potential source of unwanted coupling. All your efforts to control polarization and physically separate antennas can be largely wasted if your feedlines are radiating.

Excellent advise on how to power the Analyser.

Has anyone used one or both of these analysers, Palstar ZM30 or the
Kuranishi BR-210?

Apart from the build quality, are they any better than the MFJ-259B?

I have alot of Belden RG 174 and will send a length to anyone in this group
who want some new coax and is willing to pay the USPS Flat Rate postage.
Contact me and tell me where to send it. I'll send it anywhere the USPS
will allow.
There is no charge for the coax, nor for the "handling".
I'm not selling this stuff. I'd like to see someone use it.

Being safe while you do the calculations, or calculating the safe power handling limit? For the former, which you asked, I suggest sitting in a chair with proper ergonomic design..<grin>

But, I suspect what you're really asking is how to go about calculating the power handling limits of the coaxial structure...
Consider two factors:

1) High voltage breakdown. What's the breakdown strength of your insulator? If the two tubes are fairly large in diameter, you can probably approximate the field as the voltage divided by the difference in radii. Air breakdown is 30kV/cm in a uniform field. If the ratio of outer to inner diameters is large (so it looks more like coaxial cable), you might want to use a different formula for fields.

Don't neglect breakdown along the surface of the insulator. If the "creepage distance" is less than 3 times the free air breakdown distance, then you've got something to worry about.

2) Thermal limits. How much current is being carried by the inner conductor? What's the path to somewhere the heat can be dissipated?

For both of these you'll need to model the circuit so you know the current and voltage across your capacitor.

I guess I don't run my 259B long enough to experience battery life problems. I think the longest I've ever used it continuously is about 45 minutes. I put a full bank of 2500 maH camera batteries in it (NIMH), and have left it connected to the charger (that came with the 259B) for months on end. The batteries seem to show a full charge when I pull the unit out for use, and don't appear to be compromised by sitting on the charger for literally months at a time between uses.

I'm sure the gel cells work better, but I, for one, have had no reason to upgrade from the NIMH internal cells that I've been using for two years. Then again, I don't use it for hours on end, either.

On closer inspection, the Belden coax is RG 142 B/U, not RG 174.

do what i do, copy a known design.... the center conductor and insulation
from rg-8 (not foam type) works well and takes full power. cushcraft uses
3/16" aluminum rod inside 1/2" aluminum tubing with something that looks a
lot like rg-8 poly insulation to make a slip fit.

Hi Lumpy,

I'm fortunate to have access to a shear that cuts fiberglass/epoxy board stock reasonably cleanly. I use all double-sided stock, copper-clad on both sides. I typically set up the stop for, say, 2 inches, and make a bunch of square pieces. They'll become end pieces and partitions between "cells". Then I cut a couple 2 inch wide strips using the same setup; these will be the sides, and they are whatever length I need. The base piece is typically a quarter inch wider (or a bit more) and the same length as the sides. I plan out where I need holes, and punch them in the partitions and end pieces (or sides, if that's what I want). Then I tack one of the square pieces just short of the end of the base, so I can solder it to the base on both sides. Same on the other end. Then side pieces go in, tack-soldered to the base and the two end pieces. Avoid tacking where partitions will go. Put in partitions where you want, and tack them. Then run a bead of solder along each place where two pieces of copper-clad come together. Occasionally I'll also put in something to support coils or wires, too. Then I built the filter...soldering some parts to the copper clad for ground.

Some filters I can get by with a minimum of partitions. I would expect for a sharp cutoff filter like the "FD adjacent band" filter that I'd need to use a partition to separate any two adjacent resonators.

When I first started making filters this way, I was expecting to have to seal off the open end of each cavity. The description above only puts copper-clad on five of the six sides of each cell. I was amazed

to find that it's practically never necessary to do that. For example, I have a 1MHz bandpass filter that has stops specifically at 2MHz and 3MHz. I used it to clean up the output of a signal generator so I can test for harmonic distortion. That filter shows about 120dB attenuation at 2 and 3 MHz, in spite of the open-topped cells.

If a picture would help, I'd be happy to send one via email.

Cheers,
Tom

Jerry, US hams must be grateful to you. That is a teflon cable that costs $2.40 per foot.

I cannot profit of your generous offer as postage to Italy would be too expensive.

Hi Jerry,

From
http://www.belden.com/pdfs/03Belden_Master_Catalog/06Coaxial_Cables/06.76_81.pdf
(page 2), RG-142B/U is Belden's #83242...
Center Conductor: #18 solid, silver-coated copper-covered steel
Dielectric: TFE Teflon® Insulation
Shield: Double Silver-coated Copper Braid Shield (96% Coverage)
Jacket: Tinted Brown FEP
OD: 0.195"

Are you *sure* you want to give it away? Mouser wants $460/100ft for it!

I've also used a table saw with a VERY fine-pitch blade, set just above the table. It makes nice 90° corners. A Shop-Vac keeps the dust from getting out of hand.

I considered stubs and lumped-element filters but last year with the Machias Radio Group, we ran two stations w/o any filters... an FT1000MP on CW and TS430 on fone (http://www.geocities.com/bswadener/fd2007/). The tents were separated by about 1000'. We had almost nonexistent issues with interference.

If you want to work through design of lumped-element filters, Jim Tonne WB6BLD (http://tonnesoftware.com/) has some nifty software available. Stubs are covered in a book written by George Cutsogeorge W2VJN, "Managing Interstation Interference - Coaxial Stubs and Filters", available here: http://www.qth.com/inrad/book.htm.

No, Andy, I've been using it right out of the box since day one. I put the high capacity NIMH batteries in it the first day, plugged it in, played a while, then left it plugged in and periodically checked to see what the voltage was when I turned it on. It was obvious that it was charging and that it wouldn't cook the batteries, so I let it run....permanently. The only time the charger has been taken off the batteries is with power failures (two or three lasting a few hours) over the last few years, as well as for use periods less than 45 minutes outdoors.

I understand how people might not be able to get hours and hours of use with any internal pack, but for my uses, not exceeding half an hour at a time, I was left completely unaware that there was a battery life problem. I'll go check to see what the batteries register on startup right now...hang on...

14.1 volts with power supply (charging wall wart) disconnected.
14.4 volts with power supply connected. (batteries in place), read the screen on startup, what do you get?

10 cells at 1.4 v nominal for a full charge. It sure looks to me like the charger is working properly, and I have a full charge on the batteries. I'm sorry...I just don't see the problem. After months and months of continuous charging of the batteries (more like a couple years!) I don't see the batteries as cooked, nor do I have a problem running the unit for 45 mins at a time. The batteries seem to have a full charge right now, and show no evidence of overcharging.

I'm not sure what more I'm supposed to get ...the batteries charge to what appears to be full capacity, and the charger doesn't seem to cook them when left on for many months. I have no idea what the "on time" capacity of the 2500 maH batteries should be with my 259b. I can only say that for my requirements (less than an hour total use each time), mine works fine. I have no use for an external battery pack.

73,

...hasan, N0AN

Hi there.

My 40 mtr doublet is fed with a balanced line of 300 Ohms. Nicely tunable to 1:1 . But after twenty minutes or so the coil gets rather hot! It is a quality coil of 3 mm and shiny silvered or chromed on a ceramic body of 1 inch.

How are your experiences with a 100 W tx ? I calculate just 0.3 Amps thru it. The mind boggles on this..! Where does that heat come from ?

>
It comes from losses. Can you try different combinations of coil/capacitor settings to still get a low SWR?
Only 1 db of loss is still about 20 watts. And 20 watts is quite a bit of heat.

There will always be some degree of heating. In the best of cases,
it won't be noticeable, but that heat is from losses, and there's
always 'some'. In general, it sounds as if the tuner isn't tuned
correctly. The least amount of inductance necessary is a very good
idea! You might also check things in general, connections are good,
component 'size' is sort of at least in the 'ball-park', that sort of
thing. Keeping that feed line away from things is another idea.
Nothing 'extreme', just 'good sense'.
Not much help, but...

I once had a similar problem using a 130 foot dipole
fed with 450 ohm ladder-line on 40m. The SWR on the
ladder-line was about 15:1 and the 4:1 balun was
looking into 30 ohms. The balun presented 7.5 ohms
to the tuner and the coil got hot. That's when I
decided to come up with my no-tuner approach at:

http://www.w5dxp.com/notuner.htm

Is your 40m dipole 66 feet long fed with 60 feet
of 300 ohm twinlead through a 6:1 balun? If so,
your tuner is installed in a lossy configuration
and heating is to be expected. The simulator at:

http://fermi.la.asu.edu/w9cf/tuner/tuner.html

says that 16% of the power is lost in the tuner.
16 watts is enough to heat up a coil. Ever touch
a 15w appliance bulb when it is on?

NASA is inviting everyone to send their name to the moon on board the Lunar Reconnaissance Orbiter.

Right now you can log onto a special NASA Web site that is collecting names, which will be put on a microchip that will be integrated into the LRO.

The LRO mission is the first step in NASA's plans to return humans to the moon by 2020.

The deadline to add your name to the microchip is June 27.

http://lro.jhuapl.edu/NameToMoon/index.php

Not at all unusual.

An antenna tuner (or "transmatch" as some prefer) is a tuned circuit,
which can develop some very high circulating currents which flow
between the inductive components (e.g. the coil) and the capacitive
components (the internal capacitors, or the capacitive reactance of
the load). These high currents can result in a substantial amount of
loss in the tuner components (mostly in the coils).

>How are your experiences with a 100 W tx ? I calculate just 0.3 Amps thru it.
>The mind boggles on this..!

If I recall correctly, 100 watts is developed into a 50-ohm load via
70.7 volts at 1.4 amperes.

Those are the voltages and currents at the transmitter output. The
voltage and current relationships will be different at other points in
the circuit... at the antenna itself, and at various points inside the
tuner... because the impedances will be different.

In the case of extreme impedance transformations (e.g. transforming 50
ohms down to match a 5-ohm load, or up to a 1000-ohm load), an
antenna tuner can have to handle either very high currents (leading to
high I^2*R losses) or high voltages (leading to arcing).

The popular "T" antenna tuner configuration can be a bit tricky...
it's notorious for being able to "tune" some very difficult loads,
even down to a short circuit in some cases. In this latter situation,
the tuner is actually "tuning" its own internal losses (e.g. in the
coil). There are plenty of tales around about peoples' antenna tuners
"burning up" when this occurred - all of the transmitter power went
into heating up the coil, and melted the coil form!

> Where does that heat come from ?

From the transmitter! You may actually have several amperes of RF
flowing through the coil. The coil's series resistance at RF is

higher than it is at DC, due to skin and proximity effects.

You might be able to reduce the losses and heating by changing the length of the 300-wire line you are using, so that the antenna's feedpoint impedance is transformed into an impedance at the tuner that doesn't require extreme impedance transformation, and requires the use of lower amounts of reactance during tuning.

If I recall correctly, the ARRL Handbook has some tables (and software?) which can let you calculate a tuner's efficiency and losses, based on the impedance of the load and some reasonable assumptions about the Q of the inductor. Lower efficiency == more loss == more heating.

hi

i was just reading about airforce plans that had a trailing wire which
when fully extended was 6miles long

i was just wondering given that environment and assuming a few
varied yet unknown frequencies...

how well does such a antenna work, when assuming it is multiple
waves long?? i mean does anyone know from first hand experience how
they worked?? good bad?? just talking signal wise

i can extrapolate technically how it 'ought' to work but wonder

thanks

hi

there are a few good analizers out there assuming you are looking at
hf frequencies,

timewave makes anice unit, as does autek

mfj as mentioned here does some nice stuff

it was a tough choice for me not to many units but they are mostly
simular features depending on the type of work you need to do one
feature vs another might make a buying point with you

however i ended up w/the aea hf analysist, i got it mostly because
it could be run on batteries or adapter could be connected to a
computer after measurements to analyze data OR be connected to pc
for simutenious readouts

it was very rugged case lookes like it was ment to be dropped and
live membrane keypad so a little water mist /dust/dirt won't
gum it up

was very easy to use had both digital and graphical readouts and
the readouts were real time so i can just watch the meater and prune
/adjust antenna

aea gave me good support

thats just my 2cents i really like the timewave i just couldn't
afford it at the time but would consider one , one day never ever

saw one used.

i think the mfj are prob the lowest cost units i forgot which
but arrl recently did a shootout of the analyzers goto the arrl web
site and search the ast article their comparisons fo all the units
were really nice

if you don't need a portable unit visit arraysolutions.com they
mike a nice vector analyer that is great youll need a pc laptop to
use portabloe

good luck

I've used stubs to clear things up. I've been surprised how well they
work. Just remember what band you're on.

Another possibility is a beverage antenna. Get that as far from the
transmitting antennas as you can - though keep in mind the real estate
limitations in Field day

I thought so too, until I tried one. I was working 20 meters on a
tribander ans a KW, teh guy beside me was on a 40/30 meter fan dipole
running legal limit. Antennas were less than 50 feet apart. Without th
stub, I couldn't work period, with it, it knocked the 40 meter signal
completely out, FAPP.

I would suggest that No Spam might try an experiment, making a stub as a first try. It's simple enough that if it doesn't work, there isn't much effort wasted.

Can't say for sure why some say a stub won't work, while the one I made worked gangbusters, and cured the exact problem No Spam was looking at.

This may be - to communicate with submarines (VLF).
So your assumption that its multiple wavelengths long may be unwarranted.
It may be a quarter-wave, half-wave or any portion (or multiple) of a
wavelength.
.

I ran into that problem many years ago when they first starting
importing some off-shore VHF antennas. I ended up purchasing a 5/8-24
NF die-nut and that took care of the problem. Its very easy to use
requiring very little pressure to "chase" the threads so that a
standard PL-259 screws on without any problem.

Over the years having that die-nut has paid for itself many times for
myself and friends who ended up trying to use metric connectors with
American standard connectors.

From:

http://jproc.ca/radiostor/vlfelf.html

In the United States military, the primary means of communicating with submerged submarines is the TACAMO (Take Charge and Move Out) system which uses a fleet of aircraft. Two aircraft are always airborne - one over the Atlantic and one over the Pacific. Other aircraft are stationed on the ground and they are on a 15 minute alert. The aircraft fly 10.5 hour missions, starting at one airfield and ending at another. Random patterns are flown to mislead any unauthorized observers. The TACAMO aircraft can receive and relay signals from a number of different ground command posts. Each aircraft is equipped with a 6.2 mile long trailing wire antenna (wound on a reel) and a 100 kw transmitter operating in the VLF region. When the aircraft has to transmit a message, it banks and proceeds to fly a very tight circle. The causes the trailing wire antenna to hang vertically below. Once the message is transmitted over the VLF downlink the aircraft resumes normal flight.
The TACAMO fleet was initially comprised of the Lockheed Hercules EC130 aircraft, but these are being gradually phased out and replaced with the Boeing 747 AWACS type aircraft. These aircraft have the capability to transmit a 200 kw signal using a 2.5 mile trailing antenna. The systems described above were documented in a book printed in 1985. Due to unavailability of information, I do not know if the same system is still in use in the 1990's, but the techniques, nonetheless are quite intriguing.

Whist running a die over the thread will allow a 'normal' 259 the be screwed onto the socket it does reduce some of the thread to almost nothing, so I would not recommend that method where there is any mechanical strength required such as an antenna base.

With the velocity factor of 300 Ohms ribbon being 0.99 (take it as 1)
and using a symmetrical dipole (hence not a Windom type of antenna), to
get a low impedance at the matching unit (tuner if you like) the length
of half the dipole + the length of the feeder should be about an odd
number of quarter wavelengths.

In over 20+ years of use I have never experienced anything like that.
If you think about it, the difference between the metric and american
threads - in the case is - is slight (Look just how far you can screw
a PL-59 on the meteric socket) and a very small amout of material is
removed.

Have you really ever tried this method?

Once you try this method you see that you really have nothing to be
concerned about. (Unless you use a wrench and really apply heavy
pressure on a PL-259.) For hand tightening you'll have no problems.

What you will see if you actually try this method is that the threads will be reduced in thickness over about half the length. The reduction getting worse as you progress. The threads will have reduced to such an extent towards the end as to render then no more than bumps. Have a look at one you have done this to under a magnifying glass and you will see.

That rule-of-thumb is a linear approximation but the
actual function is not linear. Here is a graph (generated
using EZNEC) that is more accurate than the-rule-of thumb.
Using this graph, quite often one doesn't even need a tuner.

Of course, half-wavelengths of feedline are added to
the matching section length to achieve a reasonable
total feedline length.

The velocity factor of 300 ohm ribbon twinlead is approximately 0.80,
but it varies from brand to brand and lot to lot.

Jeff,

The TPI between the two standards (American and metric) - in this
case - are very close resulting in very little thread stock being
removed. In the short thread length involved here (about 1/2-inch) and
the threads are not rendered to nothing more than bumps.However, at
longer thread lengths it well could be a problem, but not at the
1/2-inch distance we are talking about here.

Again I ask, have you actually tried this?

I have used this method numerous times for myself and friends and I
have never experienced any kind of failures or problems in doing so.

That said I'm going QRT on this subject.

Yes. and I would not trust the end result to any kind of load, it is fine
for a cable connection but certainly not as a method of retaining a mobile
antenna at speed!

Perhaps the difference is in the die, and the length of thread in the die.
The thicker the die the truer the thread will be and the more pronounced the
removal of the metric thread.

The OP was suggesting a 'die nut' which will be quite thick and I suspect
would produce results similar to those I have found.

I measured the VF of 300 ohm and 450 ohm window-line from
The Wireman. The 300 ohm stuff was very close to 0.8 while
the 450 ohm was closer to 0.9

In fact the TPI's are not that close 24tpi for American (1.06mm pitch) and
1.5mm pitch for Metric fine.

==========
Tnx Roy , I thought is was about the same as for 450 ohms twin feeder.
That's what I use. The 'thumb rule' of the length of half the dipole +
length of feeder being about an odd number of quarter wavelengths for a
low impedance at the matching box (mine is an E-zee match unit) works
well for me. With 450 Ohms twin feeder you can sense the current in 1
wire with a clip-on relative RF current sensor/indicator to find a low
impedance point ,because of the large open slots. If right for a lower
freq band , the matching box takes care of the higher freq bands (also
non-harmonic bands) ,without getting 'warm'.
However with the current feeder ,for 1.8 MHz I would have to increase
the feeder length (coiled-up inside shack and kept away from metal)

Very interesting indeed.
We know that uhf and vhf are for the most part, line-of-sight communication,
with exceptions like ducting, etc...
But it would be interesting to experiment with vlf, to see what it
penetrates.

Speaking of the trailing wire - I wonder if you could trail a loop - and use
it to generate electricity from cutting earth's magnetic lines of force -
(perhaps to power the aircraft after its up to speed. I think they
experimented with the idea on one of the shuttle's orbital missions, but
didn't hear much about the results.

The metric PL259 has a pitch of 1.0 mm. It is not an ordinary metric
fine thread. (5/8 - 24 is not an ordinary fine thread either.)

The wire cutting through the magentic field will generate an EMF - a
potential difference between one end of the wire and the far end but
there is no complete circuit to tap it. If a return wire were
connected to the far end of the wire, it would generate the same value
and polarity giving no net emf (voltage) around the path. If one
could create a loop and rotate it in the field that would be a
different matter. The same concept applies to the voltage developed
between the wing tips of a (metal) aircraft.

Just received this through a ARES reflector
==========

""Strong earthquake hits China, all ham radio operators stand by PLEASE HELP TO SPREAD THE FOLLOWING MESSAGE

Strong earthquake hits China, all ham radio operators stand by A Magnitude 7.8 earthquake hits Sichuan, China on Monday, May 12, 2008 at 06:28:04 UTC. Casualties and loss unknown up to now. According to Chinese Radio Sports Association, 14.270Mhz, 7.050 and 7.060 Mhz are preserved for amateur radio emergency service in the rescue. Please spread this message as far as you can and keep the frequencies clean for emergency use. Thank you.

Yesterday, 05:57 PM
BG8AAS from Chengdu, Sichuan reported that local UHF repeater survived in the disaster. It keeps functioning from the 1st minute and more than 200 local radio hams are now on that repeater. A group of hams from Chengdu has headed for Wenchuan, the center of the quake, trying to setup emergency communication services there.

BA8AB, also from Chengdu, Sichuan, is active on the 40m emergency frequency. Up to now, no further information available from the center zone of the quake. There are a few radio amateurs there, but all of the communications have been cut out, including amateur radio.

Yesterday, 06:58 PM
Update

According to BG8AAS, local UHF repeater in Chengdu keeps busy running after the quake. It helps to direct social vehicles to transport the wounded from Dujiangyan, Beichuan, and other regions. Another UHF repeater also starts its working in Mianyan, supported by generators.
However, they are going to face a shortage of gas.

Damage in Chengdu remains in the lowest level, but the situation is very very bad in the counties around. A few towns are said to be destroyed completely. More than 7000 died in the town of Beichuan. Casualties in several other towns are still unknown and not counted in the published numbers.

It is a long and sad day.

Today, 08:31 AM
Your attention please! 14.270Mhz is now reserved for ARES in 5.12 earth quake in Sichuan, China. Please help to keep this frequency clear.

A group of radio amateurs is now transmitting from Wenchuan, the center of quake. Its signal is reported to be very weak. They tried to keep communication with BY8AA in Chengdu, seeking for all resources needed. During a contact finished a few minutes ago, they were asking for raincoats, water, tents, and outdoor living facilities.

PLEASE HELP TO FORWARD THIS MESSAGE TO ALL RELEVANT FORUMS, MAILING LISTS, AND NEWS RESOURCES. MEANWHILE, KEEP THE ABOVE FREQUENCY CLEAN FOR EMERGENCY COMMUNICATION.

Hi rb

It reads as though you are contimplating errecting a 45 or 50 foot self supporting vertical using PVC pipe to support the conductor. Dont spend much money on PVC till you try some. It bends easily. I cant imagine a 20 foot length of 1/2 inch PVC (0.850OD) supporting itself even in a mild brease, (if you could get it vertical).

But as I understand it, Mike, it was to kill something at least 4MHz away from 14MHz. That doesn't take a very high Q. The OP was asking about killing something 100kHz away, at 14MHz, and that's entirely different.

I assume yours was a 1/4 wave stub on the freq you wanted to kill, open on the free end (or else a 1/2 wave stub, shorted on the free end). If it was RG-213-size coax, I'd expect the Q at 14MHz to be about 100. I can do that at 14MHz in a coil about 1/3 inch in diameter and 1/3 inch long.

Cheers,
Tom

It will NOT work unless you guy it like crazy. It will fail at those
joints.
Even then, it is hard to pull it up vertical without it breaking. Even if
you get it vertical it will not stay that way.
One day you will look out and it will be leaning over at a 10 degree angle.
Then next day
it breaks. You will speak bad words. The neighbors will hear you.
I speak from experience from the summer of 2006.

My post was about a possible trailing loop. (Both ends accessable to the ham
on board.)
You don't have to rotate the loop - just to move it.
The aircraft is moving - thus the magnetic lines get 'cut' so to speak, so
emf gets generated.
I also heard it worked 'too well' on the shuttle - that the current was so
great that the wire burned into.

Been there tried that-
It won't work.
I tried sched 40 plumbing PVC and the gray PVC sched 40 (electrical).
Pvc is ok for a 2-meter quad - but use alum or steel mast,
you may try the top-post they use for chain-link fences - I think you can
get it in 20-ft lengths.

Incidentally, the Z0 of the "300 ohm" window-line
was considerably lower than 300 ohms and the Z0 of
the "440 ohm" window-line was about 388 ohms.

I don't recommend that, either. It is heavy and bends easily. The radio
shack TV antenna mast works better.

Sorry to be the bearer of bad news.

you can get charging and arcing in orbit from lots of other sources
(impact with charged particles, for instance). It's a pretty big issue
with large things like ISS that can build up substantial charge if
things aren't bonded together. More than one spacecraft has been lost
due to this kind of thing (Japan's Midori-2 is one case I know of).

I know they were doing this as early as '79 at least as a test. I had a little to do with AWACS data communications back then. Apparently this is no longer a security issue.

I have used the chain-link-fence-Top-Post and it worked fine. It was
available in 20-ft sections when I tried it.
Its made of Galvanized steel - thinner than sched 40 but stiff enough for a
mast for small antenna.

My first awareness of the trailing wire antennas was in about 1972. Other engineers in the group where I worked, had been working on the design and development. Considerable design effort was put into the "drog" on the end of the wire, and predicting the shape the antenna took during flight. (Computing power was not the same back then.)

Even more troubling was occasional malfunctions of the hardware that cuts loose the antenna during emergencies. When the big wire accidentally fell into the gulf, there were some unhappy fishermen!

4811. Scanner VR-500

I'm trying to restring my Dipole up in a Pine (the tree has grown about 10 ft, and the rope needs replacing) so I got out my trusty Surgical tubing wrist rocket and a 1oz egg weight tied to my 15# test fishing rod/reel (only using the bottom eye).

No matter how far I pulled back I got about 2/3s of the way up. Im estimating that is about the 35 ft level.

Shouldn't a wrister go farther ???? need bigger weight ?

Suggestions.

Stand on a ladder when you shoot?

New monofilament (more slippery than worn)?

New rubbers?

Skip the bottom eye on the pole and
feed direct from the reel?

Be sure you have a very solid wrist/arm
on the holding arm. If your hand/arm
gives while shooting, some of the
energy will be used in that wasted
hand movement.

I saw a "wrist rifle" that a guy built.
Normal WR attached to a wooden "stock"
with bazooka-like hand holds. The pouch
of the slingshot was held by a steel rod
in the "cocked" position. Just like rubber
band machine guns that kids might build.

4816. Mounting a 1.25" mast to a wooden fence ...

Newsgroup: rec.radio.amateur.antenna
Date: 2008-05-15 19:46:49 UTC
From: Bert Hyman <bert@iphouse.com>
Message-ID: <Xns9A9F965DE5527VeebleFetzer@127.0.0.1>
Source record: 25538

I should be embarrassed to ask this question. Heck, I ->am embarrassed to ask this question, but my handyman skills are non-existent, so here I am.

I have a couple of sections of 1.25" steel antenna mast, and I'd like to mount the bottom section to a wooden fence using the fence's three horizontal 2x4 braces as the mount points.

I thought I'd just go to the hardware store and pick up a few pipe clamps and I'd be done. However, it seems that no standard pipe or tube actually has an OD of 1.25", so nothing in either the electrical or plumbing sections will actually work.

As I said, my handyman skills are nil, so unless I can buy something readymade to do the trick, it's going to turn into a real hack job.

What do I look for in the hardware store to pull this off?
